PREFACE

The Cretaceous Colorado Group shales of the Western Canada Sedimentary Basin contain proven source rocks and hydrocarbon reserves, yet the details of their origin, composition, distribution, and maturity are largely unknown. This basin-scale, multidisciplinary study refines Cretaceous shale stratigraphy and provides a regional basis for further detailed exploration and exploitation of Colorado Group hydrocarbon and mineral resources.

This study integrates geochemical, biofacies, and sedimentological data to identify discrete shale formations within the previously undifferentiated Colorado Group. Detailed geochemical and facies analyses provide new information on source-rock distribution and maturity. Quantitative mineralogy and Rock-Eval data can be used to improve wireline calibrations and correlations in shale-dominated sequences. Paleoenvironmental reconstructions, including sedimentation rates, and identification of diagenetic processes within these shales will aid in the further refinement of basin evolution models of the Western Canada Sedimentary Basin and further enhance our understanding of this important hydrocarbon province.

PRÉFACE

Les shales du Crétacé du Groupe de Colorado présents dans le Bassin sédimentaire de l'Ouest du Canada renferment des roches mères et des réserves prouvées d'hydrocarbures. Cependant, on a très peu de données précises sur leur origine, leur composition, leur répartition et leur degré de maturité. La présente étude pluridisciplinaire, effectuée à l'échelle du bassin, permet de préciser davantage la stratigraphie de ces shales et de fournir une base de connaissances régionales destinée aux futurs travaux d'exploration détaillés et à l'exploitation éventuelle des ressources minérales et des hydrocarbures du Groupe de Colorado.

La présente étude intègre des données géochimiques, sédimentologiques et de biofaciès afin de mettre en évidence des formations de shales distinctes à l'intérieur du Groupe de Colorado antérieurement non différencié. Des analyses géochimiques et de faciès détaillées fournissent de nouvelles informations sur la répartition et le degré de maturité des roches mères. L'utilisation de la minéralogie quantitative et des données Rock-Eval permet d'améliorer les étalonnages des diaglyphies par câble et les corrélations dans les séquences dominées par les shales. La reconstitution des paléoenvironnements, y compris les taux de sédimentation, et la mise en évidence des processus diagénétiques ayant touché ces shales contribueront à perfectionner les modèles d'évolution du Bassin sédimentaire de l'Ouest du Canada et d'accroître notre compréhension de cette importante province de ressources en hydrocarbures.

SEDIMENTOLOGY, MICROPALAEONTOLOGY, GEOCHEMISTRY AND HYDROCARBON POTENTIAL OF SHALE FROM THE CRETACEOUS LOWER COLORADO GROUP IN WESTERN CANADA

Abstract

Shale of the Cretaceous lower Colorado Group extends across the subsurface of the Western Canada Sedimentary Basin (WCSB) and along the length of the Rocky Mountain Foothills. Four regionally mappable shale units are recognized by their distinctive geochemical, mineralogical, biofacies and sedimentological characteristics: the Late Albian Westgate, the Early Cenomanian Fish Scales, the Middle to Late Cenomanian Belle Fourche, and the latest Cenomanian to Middle Turonian Second White Specks Formation. These units were deposited in a foreland basin during a period of overall sea-level rise punctuated by periods of tectonically induced, relative sea-level falls.

The Westgate Formation is a progradational siltstone to mudstone having a low total organic carbon (TOC) content (< 2 wt %) of dominantly Type III organic matter (OM). The Westgate was deposited above storm wave-base in the Mowry Sea. The inner to middle neritic foraminiferal assemblage (*Milliammina manitobensis* Zone) and oxygen isotope composition of early diagenetic carbonate concretions indicate a cool, low-salinity water mass of Boreal affinity. Compacted sedimentation rates ranged from 1 to 6 cm/10³ yrs.

The Fish Scales Formation is a transgressive mudstone to claystone with TOC contents of up to 8 wt % of mixed types II and III OM. The basal conglomeratic layer indicates a drastic environmental change at the end of the Albian. The water column was stratified with widespread anoxic bottom waters, as is indicated by well-laminated sediments and the absence of benthic foraminifera. Compacted sedimentation rates ranged from 1 to 2 cm/10³ yrs.

The contact between the Fish Scales and the Belle Fourche formations is gradational, signifying a gradual improvement of benthic conditions. OM changes to Type III and the abundance is generally less than 2 wt%. By this time, the seaway connecting Boreal and Tethyan water masses was established but waters of Boreal affinity were dominant in the WCSB. The northwestern part of the basin was influenced by the progradation of deltaic sediments of the Dunvegan Formation. Compacted sedimentation rates ranged from 0.7 to 5.0 cm/10³ yrs.

The laminated marlstones to limestones of the Second White Specks Formation were deposited under dominantly anoxic conditions beneath an increased water column that fostered fully marine conditions. Increased water depths allowed Tethyan planktonic foraminifera and nannofossils to migrate into the WCSB. These conditions resulted in increased TOC contents of up to 12 wt% of Type II OM. Bottom currents reworked bioclastic sediments deposited below storm wave-base. Compacted sedimentation rates ranged from 1.3 to 2.5 cm/10³ yrs.

The early diagenesis of lower Colorado Group shales is dominated by sulfate reduction and methanogenesis. These microbially mediated processes resulted in the formation of pyrite, carbonate concretions and some clay mineral neoformation, primarily kaolinite. Carbonate concretions in the Westgate, Fish Scales and Belle Fourche formations are dominantly siderite, whereas those of the Second White Specks Formation are calcite. Alteration of volcanic ash and hydrolysis of K-aluminosilicates resulted in smectite, mixed-layer illite/smectite and kaolinite authigenesis.

Rock-Eval pyrolysis data indicate that, west of approximately 114° longitude, the lower Colorado Group shales are mature source rocks. The Second White Specks Formation is an effective source rock and apparently there is active localized hydrocarbon migration from the Fold and Thrust Belt. It is inferred that

hydrocarbon migration and production from the Second White Specks Formation is controlled largely by fractures.

Résumé

Les shales du Crétacé de la partie inférieure du Groupe de Colorado se rencontrent dans la subsurface du Bassin sédimentaire de l'Ouest du Canada et sur toute la longueur des Foothills des Rocheuses. Quatre unités de shales cartographiables à l'échelle régionale sont reconnues d'après leurs caractéristiques géochimiques, minéralogiques et sédimentologiques propres, et leurs biofaciès distinctifs, soit les formations de Westgate de l'Albien tardif, de Fish Scales du Cénomanien précoce, de Belle Fourche du Cénomanien moyen-tardif et de Second White Specks du Cénomanien sommital-Turonien moyen. Ces unités se sont déposées dans un bassin d'avant-pays au cours d'une période de montée générale du niveau marin, laquelle a été ponctuée par des périodes d'abaissement relatif du niveau marin provoqué par des événements tectoniques.

La Formation de Westgate est un dépôt de progradation comportant des siltstones passant à des mudstones, dont la teneur en matière organique, essentiellement de type III, est faible (inférieure à 2 p. 100 en poids). Elle s'est accumulée au-dessus du niveau de base des vagues de tempête dans la mer Mowry. L'association de foraminifères de milieu épinaltique à médio-néritique (Zone à *Milliammina manitobensis*) et la composition des isotopes de l'oxygène des concrétions carbonatées syndiagénétiques attestent la présence d'une masse d'eau froide à faible salinité, d'affinité boréale. Les taux de sédimentation compactée s'échelonnaient de 1 à 6 cm/10³ ans.

La Formation de Fish Scales est composée de matériau transgressif, allant des mudstones aux claystones dont la teneur en matière organique de types II et III mixtes s'élève à 8 p. 100 en poids. Le conglomerat de base met en évidence une modification radicale de l'environnement à la fin de l'Albien. La colonne d'eau était stratifiée et les eaux de fond anoxiques étaient répandues, comme l'attestent la présence de roches sédimentaires à lames bien développées et l'absence de foraminifères benthiques. Les taux de sédimentation compactée variaient de 1 à 2 cm/10³ ans.

Le contact entre la Formation de Fish Scales et celle de Belle Fourche est progressif, indiquant que les conditions benthiques se sont améliorées progressivement. La matière organique est de type III et sa teneur est généralement inférieure à 2 p. 100 en poids. À cette époque, la mer reliant les masses d'eau boréales et téthysiennes était déjà en place, mais les eaux à affinité boréale étaient prédominantes dans le Bassin sédimentaire de l'Ouest du Canada. La partie nord-ouest du bassin subissait les effets de la progradation des sédiments deltaïques de la Formation de Dunvegan. Les taux de sédimentation compactée allaient de 0,7 à 5,0 cm/10³ ans.

La Formation de Second White Specks comporte des marnes laminaires passant à des calcaires qui se sont déposés dans des conditions essentiellement anoxiques sous une colonne d'eau plus profonde qui a favorisé l'apparition de conditions entièrement marines. Les profondeurs accrues d'eau ont permis la migration de nannofossiles et de foraminifères planctoniques téthysiennes dans le Bassin sédimentaire de l'Ouest du Canada, ce qui a augmenté les teneurs en matière organique de type II jusqu'à 12 p. 100 en poids. Les courants de fond ont remanié les sédiments bioclastiques déposés sous le niveau de base des vagues de tempête. Les taux de sédimentation compactée étaient de l'ordre de 1,3 à 2,5 cm/10³ ans.

La syndiagenèse des shales de la partie inférieure du Groupe de Colorado est dominée par une sulfatoréduction et une méthanogenèse. Ces processus d'origine microbienne ont entraîné la formation de pyrite et de concrétions carbonatées et la néogenèse de minéraux argileux, essentiellement de la kaolinite. Les concrétions carbonatées dans les formations de Westgate, de Fish Scales et de Belle Fourche sont formées principalement de sidérite, alors que celles de la Formation de Second White Specks se composent surtout de calcite. L'altération des cendres volcaniques et l'hydrolyse des aluminosilicates potassiques ont engendré l'authigenèse de smectites, d'illite-smectite et de kaolinite.

Les données de pyrolyse Rock-Eval indiquent qu'à l'ouest d'environ 114° de longitude ouest, les shales de la partie inférieure du Groupe de Colorado sont des roches mères matures. La Formation de Second White Specks est une bonne roche mère et il se produirait localement une migration des hydrocarbures à partir de la ceinture de plissement et de charriage. On présume que la migration et la production d'hydrocarbures depuis la Formation de Second White Specks sont en grande partie contrôlées par des fractures.

Summary

Four regionally recognizable lithostratigraphic units are defined for the Late Albian to Middle Turonian interval of the Cretaceous Colorado Group within the Western Canada Sedimentary Basin (WCSB). In ascending order, these are the Westgate, Fish Scales, Belle Fourche, and Second White Specks formations. These marine shale units are characterized by their distinctive sedimentology, geochemistry, palynology, and biostratigraphy.

Stratigraphic correlations and relative ages are based on foraminifers, nannofossils and dinoflagellates. The Westgate Formation is Late Albian in age, and is represented by the *Miliammina manitobensis* Zone. The Fish Scales Formation, barren of foraminifers, contains an Early Cenomanian dinoflagellate assemblage. A diminished foraminiferal fauna of the *Verneuilinoides perplexus* Zone indicates a Middle to Late Cenomanian age for the Belle Fourche Formation. Abundant planktic foraminifers of the *Hedbergella loetterlei* Zone and nannofossils indicate that the Second White Specks Formation is latest Cenomanian to Middle Turonian in age.

In the Western Interior Seaway (WIS), foraminiferal and nannofossil assemblages indicate dynamic oceanographic conditions linked to sea-level change and variable mixing of Boreal and Tethyan water masses. These Colorado Group marine shales were deposited during a third-order eustatic rise in sea level with superimposed fourth- and fifth-order, tectonically induced, sea-level fluctuations. The Westgate Formation contains common to abundant agglutinated foraminifers and was deposited during the Mowry Sea transgression under dominantly cool, Boreal waters. The base of the overlying Fish Scales Formation is marked by the disappearance of all benthic foraminifers. A stratified water column resulted in bottom water anoxia throughout the Early Cenomanian.

Benthic conditions improved slightly during Belle Fourche deposition when sea level dropped. Subsequent sea-level rise during the latest Cenomanian resulted in the migration of Tethyan-sourced planktic foraminifers and coccoliths to the northern portion of the seaway where they dominated the faunal and floral assemblages of the Second White Specks Formation.

The Westgate Formation is characterized by multiple coarsening-upward successions, and the grain size of agglutinated foraminiferal tests reflect changes in substrate grain size. The Fish Scales and Second White Specks formations may be characterized as condensed sections. The basal bed of the Fish Scales Formation is a bioclastic, coarse grained sandstone to conglomerate layer that disconformably overlies uppermost Westgate strata. The basal contact of the Second White Specks Formation varies from conformable to disconformable. The local presence of a bioclastic layer, formed by submarine erosion, is associated with an abrupt change from a diminished agglutinated fauna to a pelagic fauna. The degree of erosion varies across the basin, but is greatest in central Saskatchewan. Other localities show a more gradational change from benthic to planktic assemblages. The Fish Scales Formation has a gradational upper contact, whereas assemblages disappear abruptly at the top of the Second White Specks Formation.

The variable and dynamic depositional environments of the WIS are reflected in the variable geochemistry of the described formations. Condensed sections (transgressive shales) which include the Fish Scales and Second White Specks formations, as well as the Santonian First Speckled Shale, are characterized by a high marine organic matter (OM) content (dominantly Type II) and C/S values with low variability. Progradational

shales (regressive) contain dominantly Type III OM and have highly variable C/S values. This is particularly evident in the Belle Fourche Formation, where prodeltaic and marine samples show extreme C/S variability.

The silicate mineralogy of the studied units is relatively uniform and comprises dominantly quartz, mixed layer I/S, kaolinite, illite, feldspars, muscovite, minor biotite, and chlorite. Pyrite is ubiquitous. Accessory minerals include apatite and anatase. Gypsum is present in the Second White Specks Formation and the First Speckled Shale. Additional sulphates include jarosite and alunite. Siderite, primarily as concretions, occurs in the Westgate, Fish Scales, and Belle Fourche formations but may also be present as a disseminated cement, particularly in well-bioturbated samples. Calcite is present in the Second White Specks Formation and First Speckled Shale as concretions and bioclastic detritus. Some samples in these units contain > 80 wt% calcite. Dolomite may also be present.

Variations in mineralogy are caused primarily by depositional environment and secondarily by diagenesis. Samples from the progradational shales (Westgate and Belle Fourche), particularly from the western margin of the WIS, contain a greater proportion of quartz silt and more detrital illite than samples from transgressive shales (Fish Scales and Second White Specks) or those samples from the basin center. Transgressive shales contain numerous bentonites, and distal samples contain a greater abundance of ash-derived matrix than proximal counterparts.

Isotope data from pyrite, carbonate concretions, and clay minerals indicate that the early diagenesis of these marine shales was dominated by sulphate reduction, methanogenesis and the alteration of volcanic ash to clay minerals. Late diagenetic processes include organic matter maturation, quartz, plagioclase, and feldspar dissolution, and continuing clay mineral authigenesis. Localized fracture formation occurred under near maximum burial conditions and may have facilitated fluid movement through these low-permeability formations.

Colorado Group shales generally are immature source rocks east of approximately 114° longitude. They are mature adjacent to and presumably beneath the Fold and Thrust Belt along the western margin of the WCSB. Transgressive shales are oil prone and progradational shales are gas prone. Rock-Eval data suggest that hydrocarbons are migrating updip from beneath the Fold and Thrust Belt. It is inferred that fracture networks control the migration of hydrocarbons to producing zones along the Fold and Thrust Belt and future recovery efficiency is linked to understanding these fracture systems.

Sommaire

Quatre unités lithostratigraphiques reconnaissables à l'échelle régionale ont été individualisées dans l'intervalle allant de l'Albien tardif au Turonien moyen du Groupe de Colorado du Crétacé dans le Bassin sédimentaire de l'Ouest du Canada. Par ordre ascendant, il s'agit des formations de Westgate, de Fish Scales, de Belle Fourche et de Second White Specks. Ces shales marins se définissent individuellement par des caractéristiques sédimentologiques, géochimiques, palynologiques et biostratigraphiques qui leur sont propres.

Les corrélations stratigraphiques et les âges relatifs sont fondés sur les foraminifères, les nannofossiles et les dinoflagellés. La Formation de Westgate remonte à l'Albien tardif à en juger par la Zone à *Miliammina manitobensis*. La Formation de Fish Scales, caractérisée par l'absence de foraminifères, renferme un assemblage de dinoflagellés du Cénomanien précoce. Une faune de foraminifères appauvrie de la Zone à *Verneuilinoides perplexus* indique que la Formation de Belle Fourche s'échelonne du Cénomanien moyen au Cénomanien tardif. La présence d'abondants foraminifères planctoniques de la Zone à *Hedbergella loetterlei* et de nannofossiles indique que la Formation de Second White Specks s'échelonne du Cénomanien sommital au Turonien moyen.

Dans la mer intérieure de l'Ouest, la présence d'assemblages de foraminifères et de nannofossiles témoigne de conditions océanographiques dynamiques reliées au changement du niveau marin et d'un mélange fluctuant des masses d'eau boréales et téthysiennes. Les shales marins du Groupe de Colorado se sont déposés au cours d'une montée eustatique de troisième ordre accompagnée de fluctuations superposées du niveau de la mer de quatrième et de cinquième ordres, d'origine tectonique. La Formation de Westgate renferme des foraminifères agglutinants fréquents à abondants et s'est déposée au cours de la transgression de la mer Mowry sous des eaux essentiellement froides de la mer Boréale. La base de la Formation de Fish Scales sus-jacente est marquée par la disparition de tous les foraminifères benthiques. La stratification de la colonne d'eau a provoqué l'anoxie de l'eau de fond tout au long du Cénomanien précoce.

Les conditions benthiques se sont légèrement améliorées au cours du dépôt de la Formation de Belle Fourche lorsque le niveau marin a chuté. La montée ultérieure du niveau marin au Cénomanien sommital a entraîné la migration de foraminifères planctoniques et de coccolithes d'origine téthysienne vers la portion septentrionale de la mer, lesquels sont prédominants dans les assemblages fauniques et floristiques de la Formation de Second White Specks.

La Formation de Westgate se distingue par de multiples successions à granulométrie croissante vers le haut; la granulométrie des tests de foraminifères agglutinants reflète les changements de la granulométrie du substrat. Les formations de Fish Scales et de Second White Specks peuvent se définir comme des sections condensées. Le lit de base de la Formation de Fish Scales comporte une couche bioclastique allant d'un grès à grain grossier à un conglomérat qui recouvre en discordance les strates sommitales de la Formation de Westgate. Le contact de base de la Formation de Second White Specks varie de concordant à discordant. La présence, par endroits, d'une couche bioclastique, formée par l'érosion sous-marine, est associée au passage abrupt d'une faune agglutinante appauvrie à une faune pélagique. Le degré d'érosion varie dans l'ensemble du bassin, mais il est particulièrement élevé dans le centre de la Saskatchewan. Dans d'autres régions, il y a passage plus graduel d'associations benthiques à des associations planctoniques. La Formation de Fish Scales présente un contact supérieur progressif alors que les associations disparaissent brusquement au sommet de la Formation de Second White Specks.

Les milieux de sédimentation variables et dynamiques de la mer intérieure de l'Ouest se retrouvent dans la composition géochimique variable des formations décrites. Les sections condensées (shales transgressifs), qui comprennent les formations de Fish Scales et de Second White Specks et le Premier shale à taches blanches du Santonien, sont caractérisés par une haute teneur en matière organique marine, essentiellement de type II, et une faible variabilité des taux de sédimentation compactée. Les shales de progradation (régressifs) recèlent principalement de la matière organique de type III et les taux de sédimentation compactée sont très fluctuants. Ces caractéristiques sont particulièrement évidentes dans la Formation de Belle Fourche où des échantillons prodeltaïques et marins montrent des taux de sédimentation compactée extrêmement variables.

La composition minéralogique des silicates des unités étudiées est relativement uniforme; elle est dominée par du quartz, de l'illite et de smectite, de la kaolinite, de l'illite, des feldspaths, de la muscovite, de la biotite en quantités mineures et de la chlorite. La pyrite est ubiquiste. Les minéraux accessoires sont l'apatite et l'anatase. Du gypse est présent dans la Formation de Second White Specks et dans le Premier shale à taches blanches. On trouve aussi d'autres sulfates comme la jarosite et l'alunite. De la sidérite, principalement sous forme de concrétions, se rencontre dans les formations de Westgate, de Fish Scales et de Belle Fourche, mais elle peut aussi prendre l'aspect d'un ciment disséminé, particulièrement dans les échantillons très bioturbés. De la calcite se rencontre dans la Formation de Second White Specks et dans le Premier shale à taches blanches sous la forme de concrétions et de débris bioclastiques. Certains échantillons de ces unités comptent plus de 80 p. 100 en poids de calcite. On trouve parfois de la dolomite.

Les variations observées dans la composition minéralogique sont attribuables d'abord au milieu de sédimentation, puis à la diagenèse. Les échantillons prélevés dans les shales de progradation (formations de

Westgate et de Belle Fourche), en particulier dans la marge occidentale de la mer intérieure de l'Ouest, contiennent des silts quartzeux et de l'illite détritique en proportions plus élevées que les échantillons provenant des shales transgressifs (formations de Fish Scales et de Second White Specks) ou du centre du bassin. Les shales transgressifs comptent de nombreuses bentonites et les échantillons distaux ont une matrice issue de cendres plus abondante que les échantillons proximaux.

Les données isotopiques tirées de la pyrite, des concrétions carbonatées et des minéraux argileux révèlent que la syndiagenèse de ces shales marins a été dominée par une sulfatoréduction, une méthanogenèse et une altération des cendres volcaniques en minéraux argileux. Les processus épidiagénétiques sont la maturation de la matière organique, la dissolution du quartz, des plagioclases et des feldspaths, et l'authigenèse continue des minéraux argileux. Des fractures se sont formées localement dans des conditions d'enfouissement quasi maximales; il se peut qu'elles aient facilité la circulation des fluides dans ces formations peu perméables.

Les shales du Groupe de Colorado sont en général des roches mères immatures à l'est d'environ 114° de longitude ouest. Elles sont matures à proximité de la ceinture de plissement et de charriage le long de la bordure occidentale du Bassin sédimentaire de l'Ouest du Canada et vraisemblablement sous cette ceinture. Les shales transgressifs sont susceptibles de donner du pétrole et les shales de progradation, du gaz naturel. Selon les données Rock-Eval, les hydrocarbures migreraient vers l'amont-pendage depuis la ceinture de plissement et de charriage. On en déduit que les réseaux de fractures régissent la migration des hydrocarbures vers les zones productrices le long de la ceinture de plissement et de charriage; l'efficacité de la récupération est donc liée à la compréhension de ces systèmes de fractures.

INTRODUCTION

The Colorado Group is the thickest and most regionally extensive succession of Cretaceous rocks in the Western Canada Sedimentary Basin (WCSB). The Colorado Group and equivalent strata form an extensive, eastward-tapering wedge of predominantly marine shales and intercalated sandstones that extend for more than 1300 km from the Rocky Mountains to the Manitoba Escarpment. This succession contains most of the clastic oil- and gas-producing units, primarily sandstones (Fig. 1), in the WCSB (Porter, 1992b). Sandstones of the Colorado Group and equivalent strata include, in ascending order, the Colony Formation, Basal Colorado Member, the Newcastle Sandstone, the Boulder Creek Formation, the Viking/Bow Island formations, the St. Walburg and Barons sandstones, the Dunvegan Formation, the Doe Creek, Pouce Coupe and Howard Creek members of the Kaskapau Formation, the Phillips and Jumping Pound sandstones, and the Cardium, Badheart and Medicine Hat formations. Because of their economic significance, the origin and evolution of these coarser clastic units are, for the most part, well-studied (see Macqueen and Leckie, 1992; and references therein; Mossop and Shetsen, 1994), yet they represent only a small fraction of the Cretaceous depositional history of the WCSB. In contrast, the enclosing shales of the Colorado Group contain a much more complete record of deposition, and thus have the potential to provide a comprehensive picture of Cretaceous paleogeography, paleoenvironments and foreland basin development. Despite this fact, relatively little is known regarding the origin and deposition of these fine grained rocks. Some of the shale units of the Colorado Group have been identified as source rocks, or potential source rocks, for much of the hydrocarbons in Cretaceous strata (Macaulay et al., 1985; Creaney and Allan, 1992). Recent advances in horizontal drilling technology allow for direct exploitation of shales as reservoirs. In addition, shales of the Colorado Group host diamond-bearing kimberlites in Central Saskatchewan (Lehnert-Theil et al., 1992; Leckie et al., 1997) and it has been suggested that Cretaceous black shales may be the source of placer gold deposits (Ballantyne and Harris, 1995). This economic potential has generated significant exploration activity focused on Colorado Group shales. The economic potential and the wealth of geological information that these rocks contain, and our relatively meager knowledge of them, are the rationale for this multidisciplinary study.

The Geological Survey of Canada undertook this study to: 1) identify distinct shale units in the studied interval, 2) evaluate the depositional and facies controls on shale composition, and 3) provide quantitative mineralogy and bulk chemical properties that may be used for wireline calibration and source rock and reservoir characterization. Geochemical, biofacies and sedimentological data have been integrated to provide a comprehensive analysis of the studied

interval and identify four distinct shale formations that make up the Albian to Turonian portion of the lower Colorado Group in the WCSB (Bloch et al., 1993).

ACKNOWLEDGMENTS

This study was funded by the Panel of Energy and Resource Development (PERD), the Geological Survey of Canada, and the Natural Sciences and Engineering Research Council (NSERC) Visiting Scientist Program. CSA was supported by NSERC research and strategic grants. The authors would like to thank Roger Macqueen for his support of this research and his administrative guidance. We are also indebted to Dave McNeil and John Wall of the Geological Survey of Canada for their assistance, taxonomic advice, and many enlightening conversations during the course of this work. Peter Adams is thanked for constructing the Saskatchewan cross-section. Technical assistance was provided by Bob Davidson, Brenda Davies, Ron Fanjoy, Brad Gorham, Al Heinrich, Ram Kalgutkar, Brian Rutley, Bill Sharman, Ross Stewart, Denise Then, Bernie Walker and Jenny Wong of the Geological Survey. In addition, we would like to thank Jun Resultay of the University of Calgary for preparing the polished mounts for electron microscopy; Peter Jones, Chang Huang and Kathy Langill of the Department of Earth Sciences, Carleton University, for SEM work and other technical assistance. Fred Longstaffe is thanked for his support and access to the Stable Isotope laboratory and insightful discussions regarding the stable isotopic data. Paul Middlestead, Jennifer Mackay and Sharon Forbes at the Stable Isotope Laboratory, Department of Earth Sciences, The University of Western Ontario, are thanked for sample processing and isotopic analyses. We are indebted to the staff of the Core Research Centre of the Alberta Energy and Utilities Board (EUB; formerly the Energy Resources Conservation Board of Alberta) in Calgary, and at the core storage facility of the Saskatchewan Geological Survey, Saskatchewan Energy and Mines, in Regina, for their assistance with sample collection. A special thanks to Mike Staniland of the GSC for his assistance in the field and his resourcefulness in solving a large number of seemingly impossible computer and database problems. We are grateful to editor Jim Dixon and reviewers Hugh Abercrombie, Dave McNeil, Wendy Warters and James White for their constructive comments.

PREVIOUS WORK

Historically, shales have been the focus of biostratigraphic studies. Previous work on the Colorado Group has evaluated various aspects of stratigraphy and biostratigraphy (i.e., Dawson, 1881; Malloch, 1911; Wickenden and Shaw, 1943; McLarn, 1944; Wickenden, 1945; Gleddie, 1949; Stott, 1963, 1967; Wall, 1967; Caldwell, 1975; Caldwell et al.,

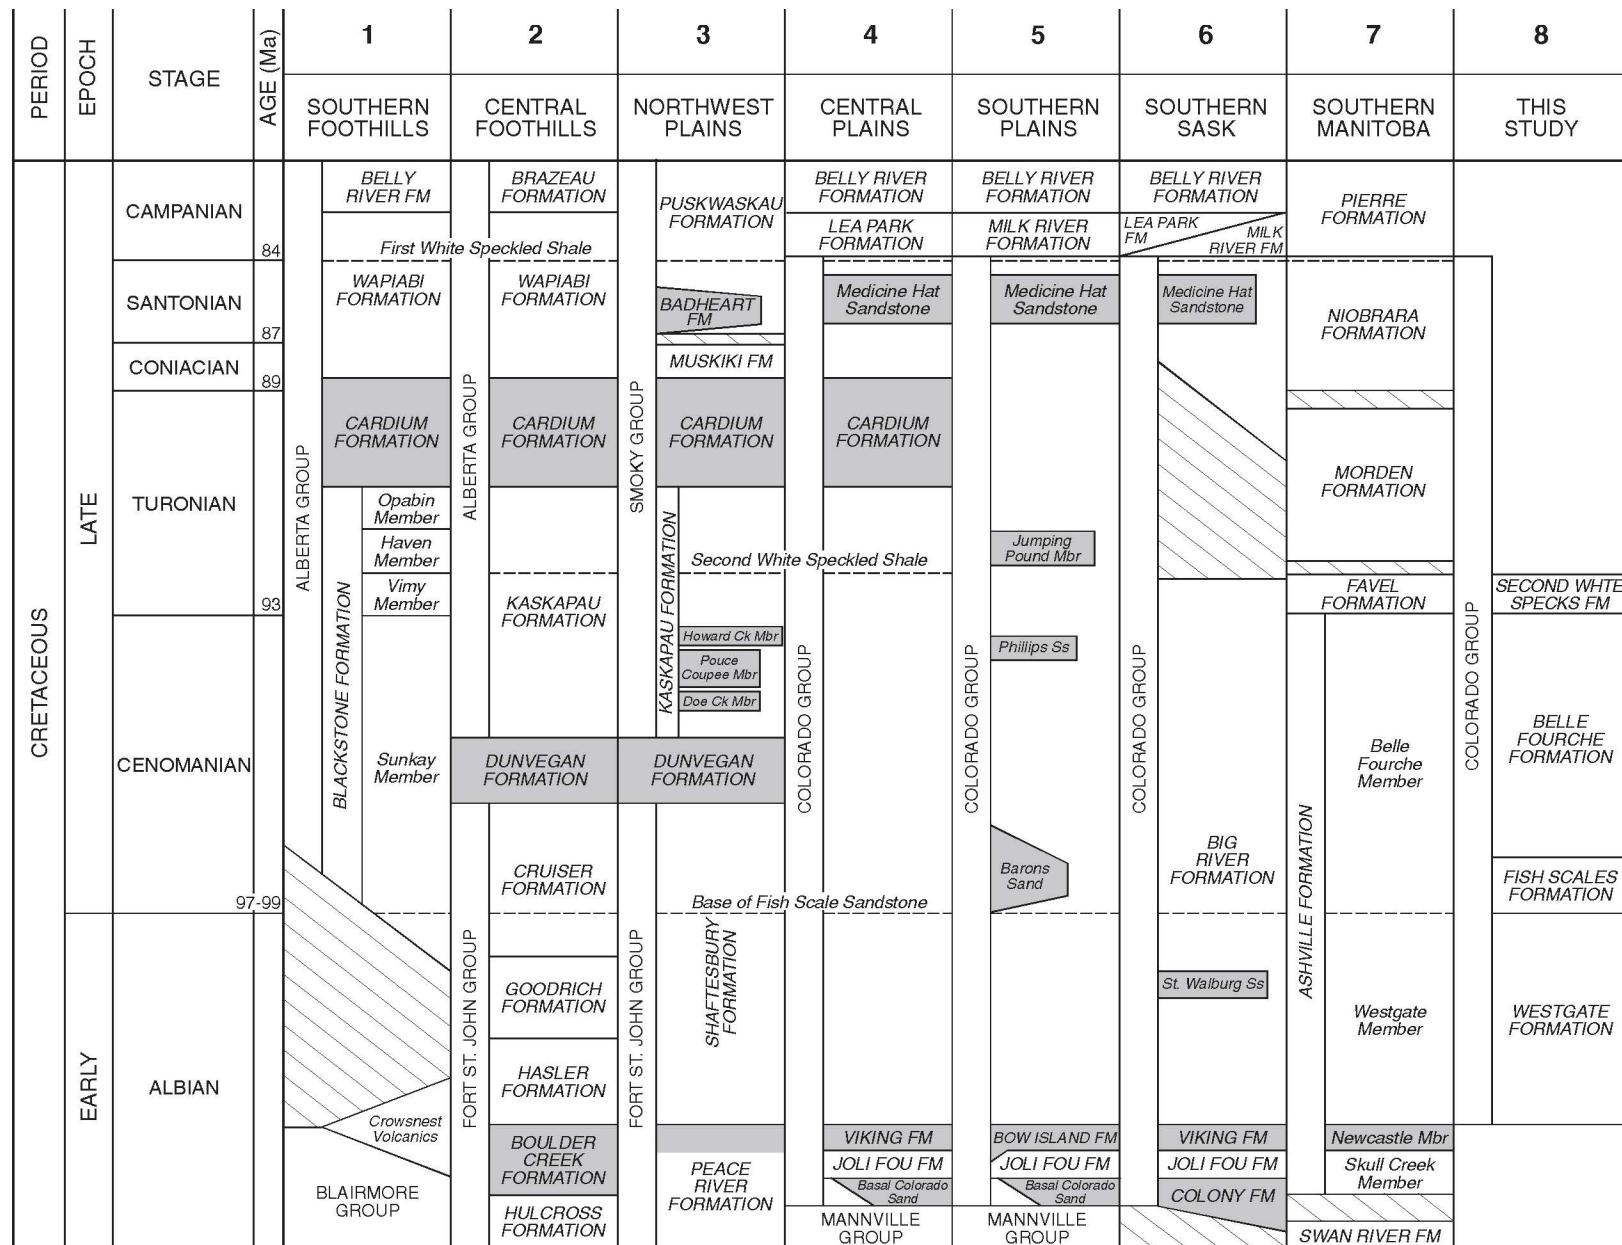

Figure 1. Stratigraphic nomenclature for the study area (after Leckie et al., 1994). Stippling indicates oil and/or gas producing sandstones of the Colorado Group and equivalent strata. Dashed lines indicate the stratigraphic tops of regionally significant wireline markers.

1978; Stelck and Armstrong, 1981; Simpson, 1982; Lang and McGugan, 1988; Bloch et al., 1993). The Cretaceous fossil zones of the Western Interior of North America are constructed primarily from shale-derived data (i.e., Cobban and Reeside, 1962; Jeletzky, 1968; Wall, 1967; Caldwell et al., 1978), and Cretaceous paleoenvironmental models of the Western Interior Seaway have been developed primarily from biostratigraphic (e.g., Hattin, 1965; Kauffman, 1969; Schröder-Adams et al., 1996) and geochemical data (Cadrin, 1992). The general architecture of the Colorado Group succession was recently described (Leckie et al., 1994). However, virtually no information regarding the origin or composition of Cretaceous shales of the Western Interior has been extracted from these rocks. Numerous studies have investigated particular aspects of shale geochemistry, such as smectite–illite diagenesis or concretion formation, but have not considered the bulk chemistry or mineralogy of the entire rock. Notable exceptions to this in the Western Interior are the studies of Rubey (1931), Campbell and Oliver (1968), Schultz et al. (1980), Whittaker et al. (1987), and Williams and Bayliss (1988).

The Cretaceous of the WCSB is a major petroleum producer (see Porter, 1992a; for a review) and exploration and exploitation of this resource extends back over two centuries. The first descriptions of Cretaceous coal- and bitumen-bearing strata were made in the late 18th and early 19th centuries (Porter, 1992a, and references therein). Cretaceous shales along the Peace River were first described by Selwyn (1877); and the first documentation of Cretaceous shales in the subsurface of the WCSB occurred in that same year (see Porter, 1992a). Gas production from the Cretaceous Milk River sandstone began in 1883 (Dawson, 1886). Current estimated conventional reserves for Colorado Group and equivalent strata total $3.706 \times 10^8 \text{ m}^3$ of oil and $6.032 \times 10^{11} \text{ m}^3$ of gas (Porter, 1992b). Various aspects of the Colorado Group petroleum system have been described (Macaulay, 1984a, b, c; Allan and Creaney, 1988, 1991; Barclay and Smith, 1992; Creaney and Allan, 1990, 1992) that highlight the economic significance of this interval.

REGIONAL STRATIGRAPHY

The Colorado Group was deposited over a period of 25 to 30 m.y., from Albian through Santonian time, when sea level was globally high (Haq et al., 1988; Kauffman, 1977). Specific sea-level maxima occurred during the Late Albian, Early Turonian and middle Santonian (Caldwell and North 1984; Haq et al., 1988). During this part of the Cretaceous, deposition was coincident with a regional tectonic downflexing of the western margin of the North American craton (Lambeck et al., 1987) that resulted in the development of an extensive north–south-trending foreland basin (see summary in Leckie and Smith, 1992).

The Colorado Group unconformably overlies the Mannville Group in the subsurface of central and southern Alberta, the Cantuar and Pense formations in southern Saskatchewan, and the Swan River Formation in southern Manitoba (Fig. 1). The strata are overlain conformably to disconformably by the Milk River and Lea Park formations in the central and southern plains of Alberta and Saskatchewan, and the Pierre Formation in southern Manitoba. In the southern Foothills, Colorado-equivalent Alberta Group strata unconformably overlie the Crowsnest Volcanics and Blairmore Group. In the central Foothills, Colorado Group equivalents include most of the Fort St. John Group, the Dunvegan Formation, and most of the Alberta Group (Fig. 1).

The Colorado Group contains seven shale formations of Late Albian to Santonian age. In ascending order, these are the Joli Fou (Skull Creek), Westgate, Fish Scales, Belle Fourche, Second White Specks (Favel), Morden and Niobrara formations. In southern Manitoba, the Westgate and Belle Fourche formations have member status and comprise the Ashville Formation; the Fish Scales Formation is not recognized as a distinct stratigraphic unit.

Shales of the Colorado Group are intercalated with numerous sandstones that reflect sea-level changes within the WCSB. In ascending order, these are the Basal Colorado Sandstone (Colony Formation), Viking Formation (Peace River and Bow Island formations), St. Walburg, Barons, Phillips and Jumping Pound sandstones, and the Cardium and Medicine Hat (Badheart) formations.

This study focuses primarily on the lower portion of the Colorado Group, which was deposited from Late Albian to Early Turonian time, and includes the Westgate, Fish Scales, Belle Fourche and Second White Specks formations. The rocks of this interval will be referred to informally as the lower Colorado Group. Inclusive in this interval are the regionally extensive Base of Fish Scales and Second White Specks wireline markers. Additional geochemical data from the Joli Fou, Viking and Morden formations and the First White Speckled Shale are also included.

ANALYTICAL METHODS

Prior to this study, most of the Colorado Group in the subsurface of Alberta was undifferentiated and there was little information to guide a sampling program. The EUB well database was searched to provide a list of cores that intersected the Colorado Group. Because of the variable thickness and scarcity of information, it was decided to limit our initial investigation to the interval that extends from the top of the Viking Formation to the Second White Specks wireline marker (Fig. 1). This interval also contains the

boundary between the Lower and Upper Cretaceous, the regionally recognized Fish Scale Marker Bed, Fish Scales Zone, or "Base of Fish Scales" (Gleddie, 1949). Cores that contain a significant thickness (generally more than 10 m), or that encompass major changes in log characteristics, were initially selected to provide stratigraphic control. Additional cores were added at a later time to provide better geographic sample control. The cores used in this study are listed in Table 1 and their distribution within the study area is shown in Figure 2.

Each selected core was examined to provide a description of the macroscopic properties of the sediments including lithology, sedimentary structures, the degree of bioturbation and the presence of observed fossils and ichnofossils. The core logs are provided for reference in Appendix A. Samples of up to 50 g were collected from the cores at regular intervals of one to five metres. Sampling frequency was increased near lithological boundaries to better assess

changes at these contacts. Most samples are identified with a six digit number and may be located by matching the first four digits with the Legal Subdivision (LSD) and section numbers of the cores listed in Table 1. The locations of the remaining samples are described in Caritat et al. (1994a), or Bloch and Leckie (1993).

Selected outcrops of Colorado Group-equivalent strata were also measured and sampled during the course of this study. Rock-Eval and biofacies analyses were done on many of these samples, but other geochemical analyses were not done. Organic-rich, pyritic black shales undergo significant weathering at surface and near-surface conditions. Organic matter is degraded (Leythauser, 1973) and the oxidation of pyrite may enhance mineral alteration. Sulphur is mobilized with groundwater flow and the formation of kaolinite and gypsum perturbs the major element chemistry and mineralogy. For these reasons, extensive geochemical analysis of outcrop samples was not done.

Approximately 20 g of each sample was allotted for geochemical analysis. Figure 3 provides a summary of sample use and indicates the overall analytical procedure. Sample preparation and geochemical analyses were done at the Geological Survey of Canada (Calgary). Additional analyses were done at the Department of Geology and Geophysics, The University of Calgary. Isotopic analysis was done at the Laboratory for Stable Isotope Studies, Department of Geology, The University of Western Ontario.

Rock-Eval pyrolysis (Espitalié et al., 1977; Peters, 1986) was performed in duplicate on pulverized shale samples, using standard procedures on a DELSI Rock-Eval II/TOC apparatus. Information thus obtained includes the type of organic matter (oxygen and hydrogen indices), its maturity (T_{max}), and the amount of total organic carbon (TOC) contained in the sample. Simple guidelines for interpreting Rock-Eval pyrolysis data are given in Table 2.

X-ray diffraction (XRD) was carried out on disaggregated and gently ground bulk shale and bentonite samples, and on their clay fractions (< 2.0 and < 0.2 μm equivalent spherical diameter) obtained by ultrasonic dispersion in distilled water and centrifugation. XRD results were obtained using a Philips PW1700 automated powder diffraction system with Fe-filtered $\text{CoK}\alpha$ radiation generated at 40 kV and 30 mA. Bulk, unoriented samples were scanned from $4^\circ 2\theta$ to $64^\circ 2\theta$ and clay fraction samples were scanned from either 2 or 4 $^\circ 2\theta$ to $40^\circ 2\theta$ with an increment of $0.05^\circ 2\theta$ at a recording speed of $1^\circ 2\theta/\text{cm}/50 \text{ sec}$. Clay-fraction diffractograms were obtained under conditions of ambient humidity (~ 45% relative humidity), low humidity (~ 0%), ethylene glycol saturation, and after heat treatment (550°C for 1 hour). Some clay separates were run from $4^\circ 2\theta$ to $64^\circ 2\theta$ to evaluate 00ℓ peak positions and Bragg behavior of clay minerals in mixtures (see Moore and Reynolds, 1989).

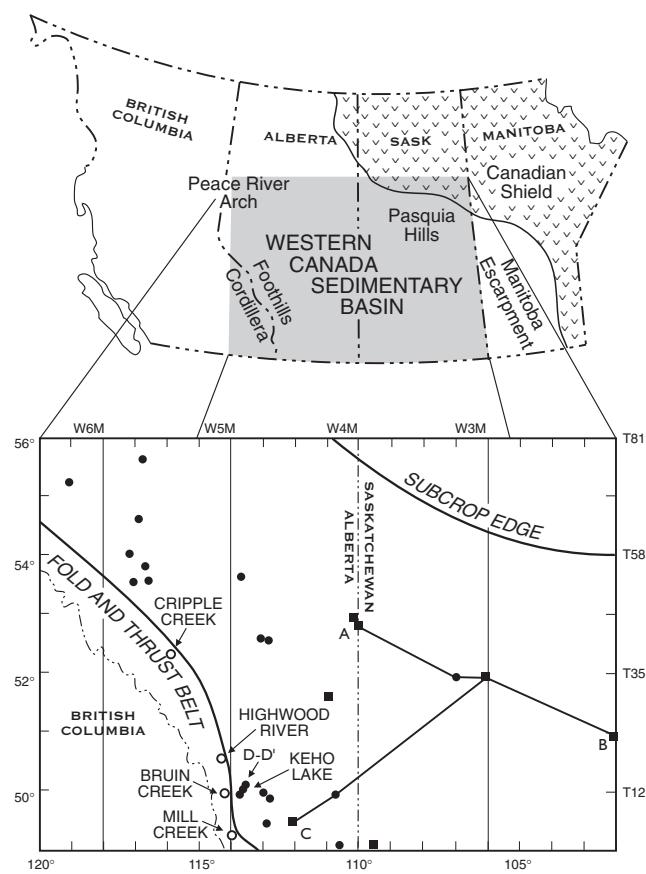

Figure 2. Study area (stippled) with major physiographic elements and the location of cored wells (see Table 1) from which sample material was selected. Square symbols denote reference sections (see Bloch et al., 1993; and Schröder-Adams et al., 1996). Lettered cross-sections A-B, B-C, and D-D' refer to figures 29, 36, and 37, respectively.

Bulk rock chemistry was determined by X-ray fluorescence (XRF) for ten major oxides on crushed shale (Tables 3, 4) and bentonite (Table 5) samples prepared by

standard techniques (Baedecker, 1987). Analytical precision on replicate analyses of 1 g samples is less than 0.9 wt% for SiO₂, 0.5 wt% for Na₂O, 0.2 wt% for Al₂O₃ and 0.1 wt% for

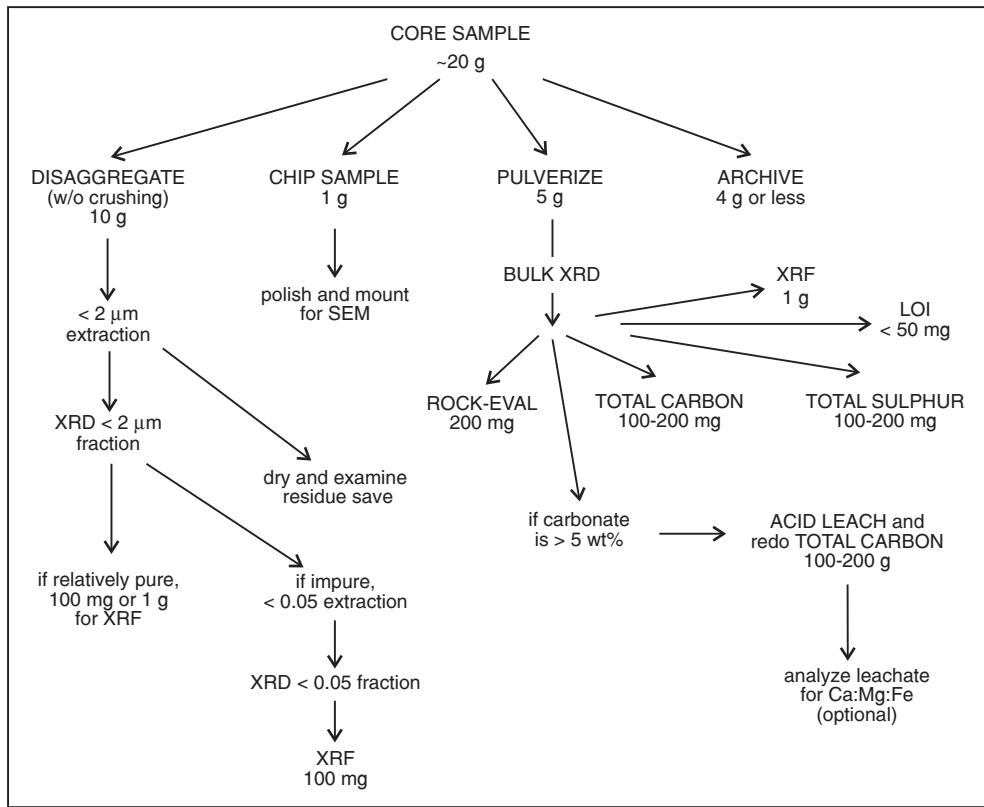

Figure 3. Flow chart of sample preparation procedures.

the other elements. Loss on ignition (LOI) was determined by combustion and thermogravimetric analysis, with a precision better than 0.7 wt%. XRF analysis of $< 0.2 \mu\text{m}$ and $< 0.1 \mu\text{m}$ clay fractions, previously characterized by XRD, was undertaken for a subset of samples in order to constrain clay mineral compositions. Because of the small amount of sample available, 100 mg aliquots were used and duplicate samples generally could not be made. Analytical error from replicate analyses of the primary standard (GSP-1), as determined by comparison with published values (see Abbey, 1980), are within 0.4 wt% for all oxides. However, analytical precision for unknowns is significantly higher, especially for Na, because of the reduced sample size. Based on the analysis of one set of duplicate beads (see Table 4; #063419), relative errors for SiO_2 , Al_2O_3 , Fe_2O_3 and Na_2O are 5, 13, 17 and 79%, respectively.

Total carbon was determined using a LECO WR-12 apparatus. Total sulphur was analyzed on a LECO-32 Sulfur Determinator using standard techniques (see Baedecker, 1987). Carbon and sulphur analyses were run in duplicate and analytical precision is 0.2 wt% and 0.05 wt%, respectively, for carbon and sulphur abundances up to about 8 wt%.

nr - not reported

nm - not measured

Bulk XRD indicates that some samples contain a significant amount of calcite and dolomite. The amount of a carbonate mineral is determined from the total inorganic carbon (TIC) in the rock. TIC is calculated by subtracting

TOC from the total carbon value. If the amount of carbonate is small (< 5 wt%), the error involved in this estimation of TIC is small. However, when carbonate minerals are a significant component, or there is more than one carbonate

mineral present in the sample, then it is necessary to determine the Ca:Mg:Fe values of the carbonate component and mass balance these against TIC to determine individual carbonate mineral compositions. For samples with these characteristics, an additional aliquot of crushed material (~5g) was treated with 40 ml of hot HCl (~100°C). The leachate was filtered (Whatman #40), extended to 100 ml and analyzed by atomic absorption for Ca, Mg and Fe concentrations. A portion of the residue was dried and analyzed for total carbon as above.

Mineral matrix effects can affect the accuracy of Rock-Eval parameters (Peters, 1986), particularly the presence of carbonate minerals. To assess the accuracy of TOC values determined by Rock-Eval, a subset of carbonate-bearing samples were acid-leached and the total carbon determined by combustion, as above. These results were compared with Rock-Eval TOC values as determined from untreated samples.

Polished sections were prepared from epoxy-impregnated core samples. Back-scattered electron microscopy (BSEM), using a Cambridge Stereoscan 150 electron microscope equipped with an 8 kV threshold annular back scatter detector, provided petrographic information. This was supplemented by energy-dispersive X-ray (EDX) analysis for qualitative mineral identification.

A linear programming method was used to determine the mineralogy of the shales and bentonites from their bulk chemical composition, and to estimate clay mineral compositions from the < 0.2 µm XRF analysis results (Table 6). Linear programming distributes the analyzed oxides according to a set of (linear) equations, which are solved simultaneously using the mathematical method known as linear optimization. The development and use of this method is fully described in Caritat et al. (1994b).

Samples for carbon and oxygen isotopic analysis were selected from hand samples of concretions and core slabs with fracture-fill carbonate cement. The hand samples were subsampled by milling small amounts of material with a dental drill and analyzed by XRD for sample purity. All samples (calcite, dolomite and siderite) were reacted with anhydrous phosphoric acid using standard techniques and fractionation factors appropriate for each mineral at the given reaction temperature (Friedman and O'Neil, 1977; Rosenbaum and Sheppard, 1986). The evolved CO₂ was analyzed on a VG-Optima mass spectrometer at the Laboratory for Stable Isotope Studies at The University of Western Ontario. Analytical results are given in standard delta (δ) notation relative to the Pee Dee Belemnite (PDB) standard for carbon and Vienna Standard Mean Ocean Water (SMOW) for oxygen (Table 7). NBS -19 values of 1.92‰

PDB for carbon and 29.07‰ SMOW for oxygen are obtained routinely. Replicate (n = 8) analyses of samples (unknowns) indicate a standard deviation (2 σ) for carbon and oxygen of less than 0.005‰ for calcite and 0.05 and 0.09‰, respectively, for siderite.

Samples for sulphur isotopic analysis were selected from a number of cores to construct vertical profiles across the basin (Table 8). Reduced sulphur was extracted from whole rock powders using a modified chromate reduction technique (Canfield et al., 1986; Tuttle et al., 1986). This method is reduced-sulphur specific and extracts only S⁰ and mono- and di-sulphide sulphur as H₂S, which is subsequently trapped as Ag₂S. Sulphide sulphur is then oxidized to SO₂ for analysis (Ueda and Krouse, 1986). Sulphur isotopic analysis was done on a VG - 602 mass spectrometer at the Laboratory for Stable Isotope Studies at The University of Western Ontario. Results are reported relative to the Canyon Diablo Troilite (CDT) standard in standard δ notation. Replicate analyses (n = 9) of an internal laboratory pyrite standard, processed identically to the unknowns, indicate a precision of $\pm 0.3\%$ CDT. Standard NBS-123 routinely gives values of 17.4 \pm 0.4‰.

Samples from seven reference wells and two outcrop sections were prepared for foraminiferal analysis utilizing the method of Then and Dougherty (1983) and washed over a 63 µm sieve. Individual specimens were handpicked for identification. The foraminiferal listings (Appendix B) reflect the total number of specimens per sample where sample volumes vary slightly. Poorly preserved specimens, which are not unequivocally identifiable, are not included in the total counts. Abundance estimates of bivalve shell prisms, algal cysts and fish remains in the sand-sized fraction, which are important for environmental interpretation, are listed under 'Miscellaneous components'.

Permanent slides of nannofossils were examined under a light-microscope. Slide preparation techniques were modified from those of Edwards (1963), Stover (1966), Gartner (1968), and Smith (1981). Counting techniques varied with the abundance of coccoliths noted during preliminary scans. If coccoliths were abundant, a half-slide scan was performed; otherwise a full slide scan was used. Total numbers of coccoliths per sample are listed in Appendix C.

Palynology samples were prepared from the 10-35-45-2W4 well. Standard acid-processing techniques (Barss and Williams, 1973) were used followed by heavy liquid flotation and sieving to concentrate dinoflagellates in the > 45µm and the 20µm–45µm fractions. Dinoflagellate plates appear in Appendix D.

Table 6

Calculated shale, mixed-layer I/S and bentonite-smectite compositions from XRF data

RESULTS

Rock-Eval pyrolysis

Rock-Eval data for all Colorado Group samples are given in Appendix E. On a pseudo Van Krevelen diagram (Fig. 4), individual formations show distinct populations of organic matter type. The Westgate Formation contains predominantly Type III organic matter with Hydrogen Indices (HI) generally less than 250 mgHC/gOC. The Fish Scales and Belle Fourche formations show a bimodal distribution containing Types II and III with HI values up to about 450

mgHC/gOC. In the Belle Fourche Formation, most of the Type III organic matter is in samples that come from the northwest part of the study area. The Belle Fourche samples are characterized as pro-deltaic (Caritat et al., 1994a) and are the most proximal of depositional environments for the formation. Samples containing dominantly Type II organic matter are generally from the upper part of the Belle Fourche formation – a transition zone to the overlying Second White Specks, which contains predominantly marine (Type II) organic matter with HI values generally greater than 250 mgHC/gOC.

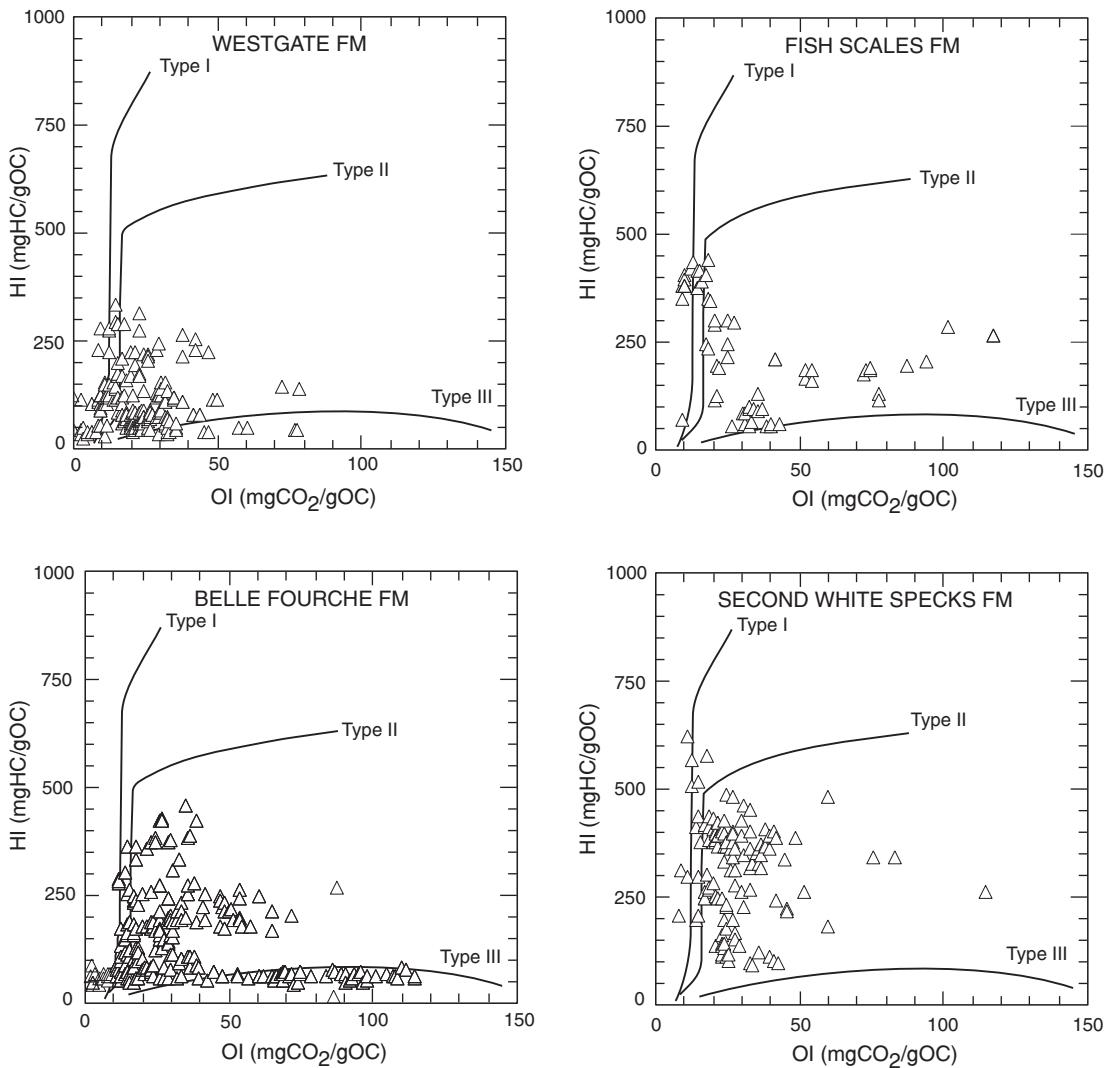

Figure 4. Pseudo van Krevelen diagram for the Westgate, Fish Scales, Belle Fourche, and the Second White Specks formations.

Bulk X-ray diffraction

The mineralogy of the Colorado Group dominantly comprises detrital quartz, feldspars and a suite of clay minerals. The clay minerals are mixed-layer illite/smectite (I/S), kaolinite, illite, and minor chlorite. The mineralogy will be discussed in detail in subsequent sections. Other major components include variable amounts of siderite, dolomite, calcite, pyrite, jarosite, gypsum, and apatite. Accessory minerals include biotite, muscovite, glauconite, zeolites, zircon, and oxides of Ti (rutile, anatase, brookite), with trace amounts of sphene, ilmenite and leucoxene.

Whole rock geochemistry - XRF

The results of geochemical analysis by XRF on whole-rock shale, clay separates and bentonites are given in Tables 3, 4, and 5, respectively. Samples designated with a two letter

prefix were analyzed at the Department of Geology and Geophysics, The University of Calgary. The results and interpretation of these samples (Caritat et al., 1994a) are included herein as part of a complete presentation of the Colorado Group geochemical data.

The chemical composition of Colorado Group shales is variable and reflects the variable depositional environments and the mineralogy of the different formations (Bloch et al., 1993; Schröder-Adams et al., 1996), particularly the calcareous Second White Specks Formation. An examination of some indicator oxide cross-plots highlights these differences. Figure 5a indicates that most samples contain between 50 and 75 wt% SiO₂ and 13 to 18 wt% Al₂O₃ showing trends towards 100% and 0% SiO₂. These trends reflect the mixing of quartz silt and carbonate, respectively, with a clay-mineral matrix. As indicated by XRD, this matrix is composed of I/S, kaolinite, and a 10 Å mineral, probably illite, with minor chlorite. K₂O varies

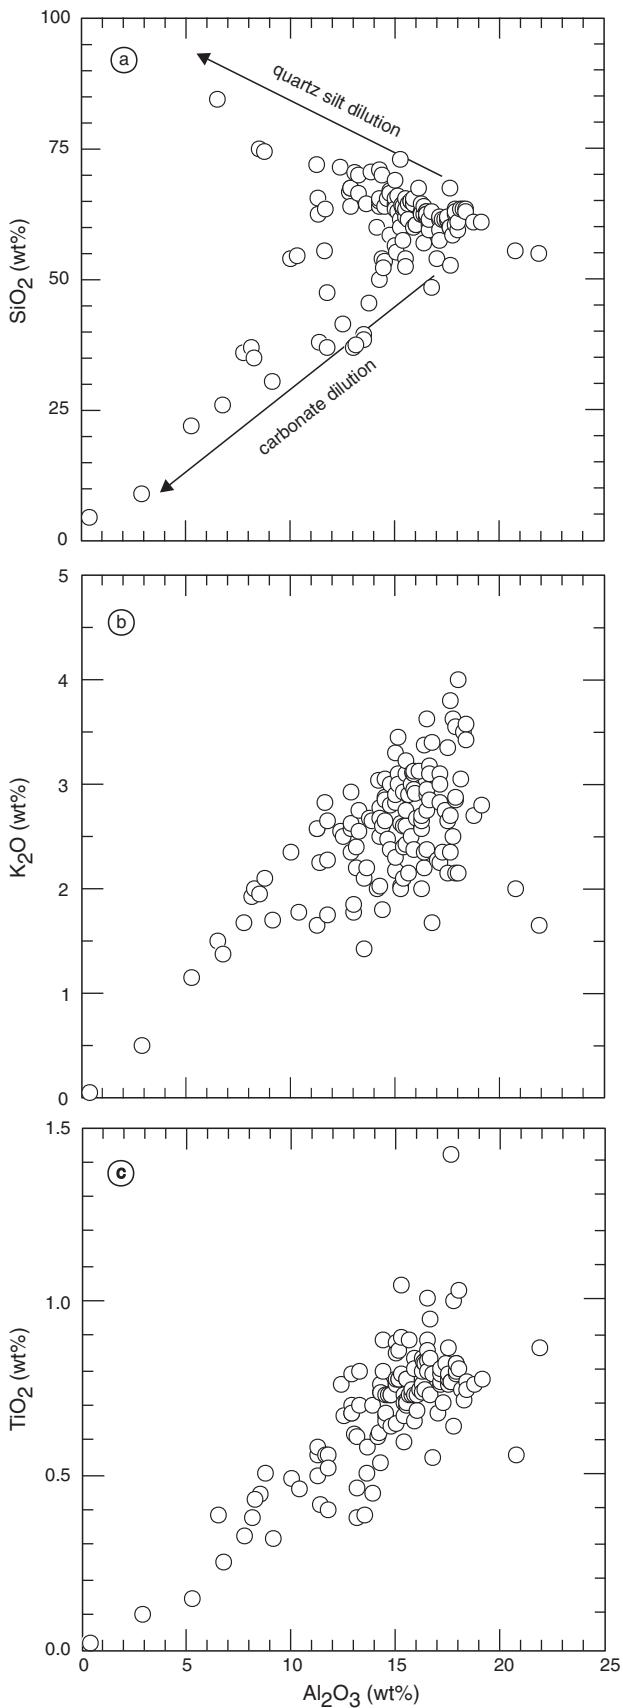

Figure 5. Bulk-chemical element crossplots for all units. See text for discussion.

from ~ 0 to > 4.0 wt% (Fig. 5b) with most samples containing between 2 and 4 wt%. TiO_2 ranges from ~ 0 to ~ 1.5 wt% with most samples between 0.5 and 1.0 wt% (Fig. 5c). Samples with low K_2O (< 1.5 wt%) and TiO_2 values ($\sim < 0.4$ wt%) generally correspond to those diluted with quartz silt or carbonate.

Total organic carbon and sulphur

The results of TOC and total sulphur analyses on whole rock samples are included in Table 3. The accuracy of TOC values as determined by Rock-Eval is assessed by comparing TOC values determined by Leco combustion on acid-leached samples with those from Rock-Eval. The results are shown in Figure 6. The correlation coefficient is 0.95 but the slope is less than one and there is a positive y- (acid treated) intercept. Rock-Eval TOC values are affected by absorption on clay minerals of the volatized organics (Peters, 1986). At low TOC values (~ 0.5 wt%), the significance of this effect is reflected in the positive y-intercept of Figure 6. These results suggest that at these low TOC values (< 0.5 wt %), Rock-Eval TOC values may significantly overestimate the organic carbon content. The magnitude of this error within the context of bulk chemistry, however, is small.

More significant is the slope of the regression in Figure 6. A slope of $m < 1$ indicates that with increasing TOC (> 6 wt%) in carbonate-rich samples, Rock-Eval pyrolysis may significantly overestimate TOC with 10–15% relative error at TOC values of ~ 7 wt%. These data indicate that

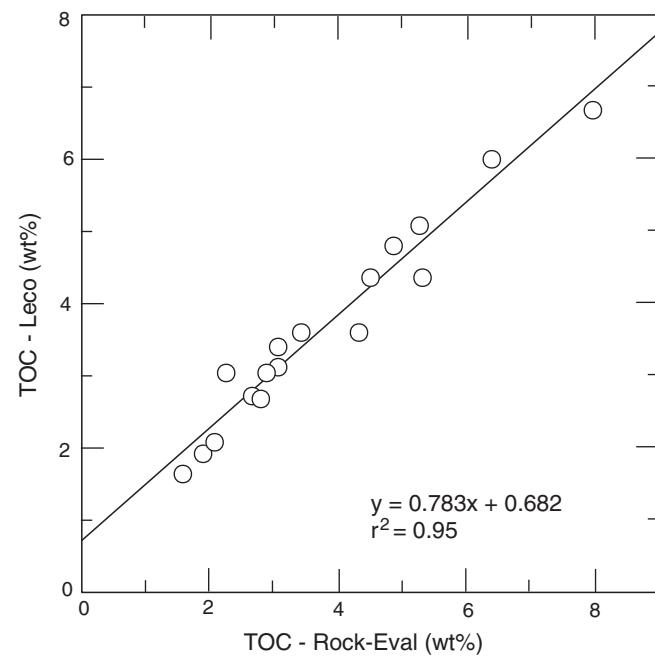

Figure 6. TOC measured by Leco combustion on acid-treated samples versus TOC measured by Rock-Eval pyrolysis.

carbonate-bearing, TOC-rich samples should be acid-treated and reanalyzed by combustion after initial Rock-Eval screening.

TOC and sulphur (S) data are shown in Figure 7. Two groups of shales are identified. Group I (Joli Fou, Viking,

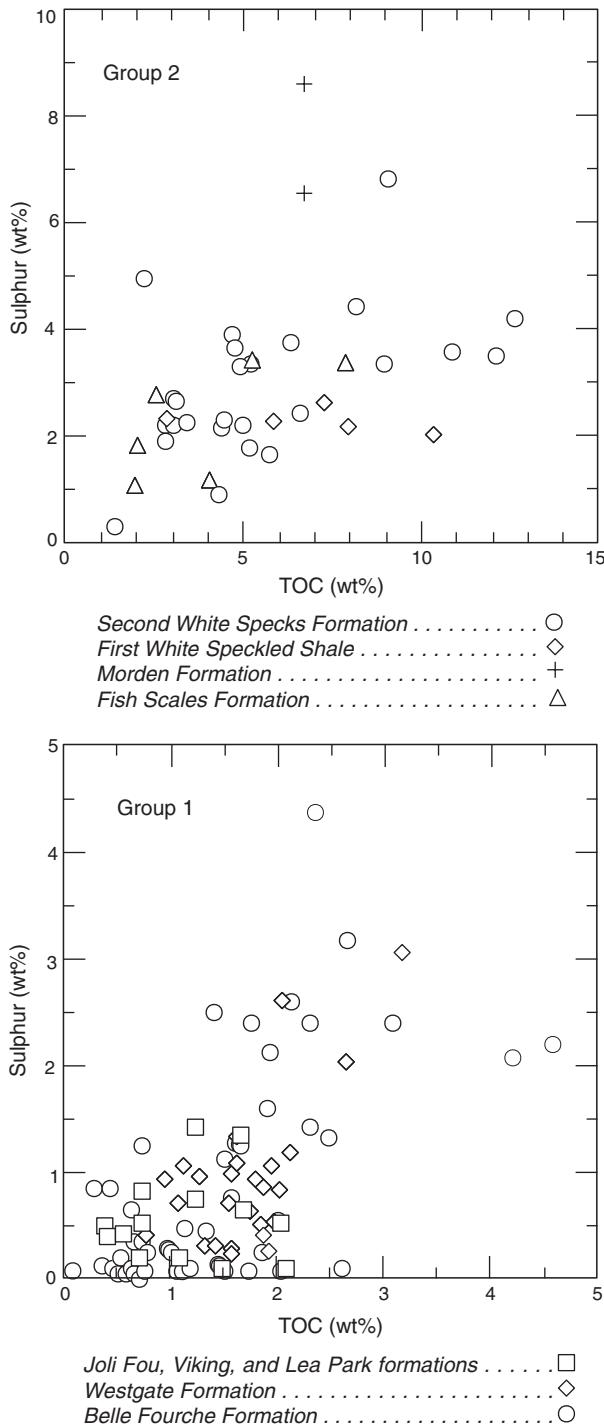

Figure 7. Carbon and sulphur systematics for shales identified as transgressive (Group 2) and progradational (Group 1). Note different scales for axes.

Westgate, and Belle Fourche formations) are characterized by low S (< 1.5 wt%) and TOC (< 2.0 wt%) values, whereas Group II (Fish Scales, Second White Specks, Morden formations and First Speckled Shale have high S (> 2.0 wt%) and TOC (> 2.0 wt%) values. This correlates with the Rock-Eval data (Fig. 4) that indicate dominantly Type III organic matter in Group I and Type II in Group II. An Fe–S cross-plot (Fig. 8) shows a similar grouping of the shale units. Group I contains more Fe and plots well away from the stoichiometric pyrite line. Group II contains less Fe and more S and plots close to the pyrite line. The Morden Formation shows a distinct enrichment in both Fe and S.

Sulphide and sulphate

The dominant sulphur-bearing mineral in the Colorado Group is pyrite, which is typically the only detectable sulphur-bearing mineral. In some samples, however, sulphate minerals are detected by XRD. For these samples, speciation of sulphur is necessary to accurately determine mineral modes. The quantitative determination of sulphide, SO and sulphate is a laborious and time-consuming task (Tuttle et al., 1986) and not suited to the processing of a large number of samples that are involved with a regional study. To circumvent this problem, a calibration method was used to estimate the amount of sulphide and sulphate in samples with multiple sulphur-bearing species. The amount of pyrite in a sample is calculated by converting the S content to stoichiometric pyrite ($S (\text{wt\%}) / 0.5345$). This value is plotted against the 0.270 nm intensity as determined by XRD. As shown in Figure 9a, samples that contain only pyrite show a very good correlation with the 0.270 nm diffraction intensity. This set of samples is then used to determine an equation by linear regression for calculating the pyrite abundance from the 0.270 nm intensity (Fig. 9b). The resulting abundances are used in subsequent calculations (see below). Graphical assessment of the error associated with this kind of calibration suggests it could be as high as 50% (shaded area, Fig. 9b) when pyrite abundances are 4 wt% or less. A small positive x-intercept results from this regression, suggesting a slight excess of sulphur assigned to pyrite. This occurs because of the presence of undetected sulphur-bearing species and/or organic sulphur. It should be noted that the presence of apatite, which has a peak at 0.271 nm, invalidates this correction method. If detectable amounts of apatite are present or the peak at 0.270 nm is not sharp and distinct, an alternative pyrite peak should be used.

Ca-Mg-Fe in carbonate

Twelve samples with variable amounts of total carbonate and generally more than one carbonate mineral were treated with HCl and the leachate analyzed for Ca, Mg, and Fe. The concentrations were converted to oxide wt% and assigned to

CaCO_3 , MgCO_3 , and FeCO_3 . These end-member components were then used to determine the abundance of ideal calcite (CaCO_3), dolomite (CaMgCO_3), and siderite (FeCO_3) by assigning CO_2 , as determined from the carbon analysis. Calcite and dolomite are the dominant carbonate

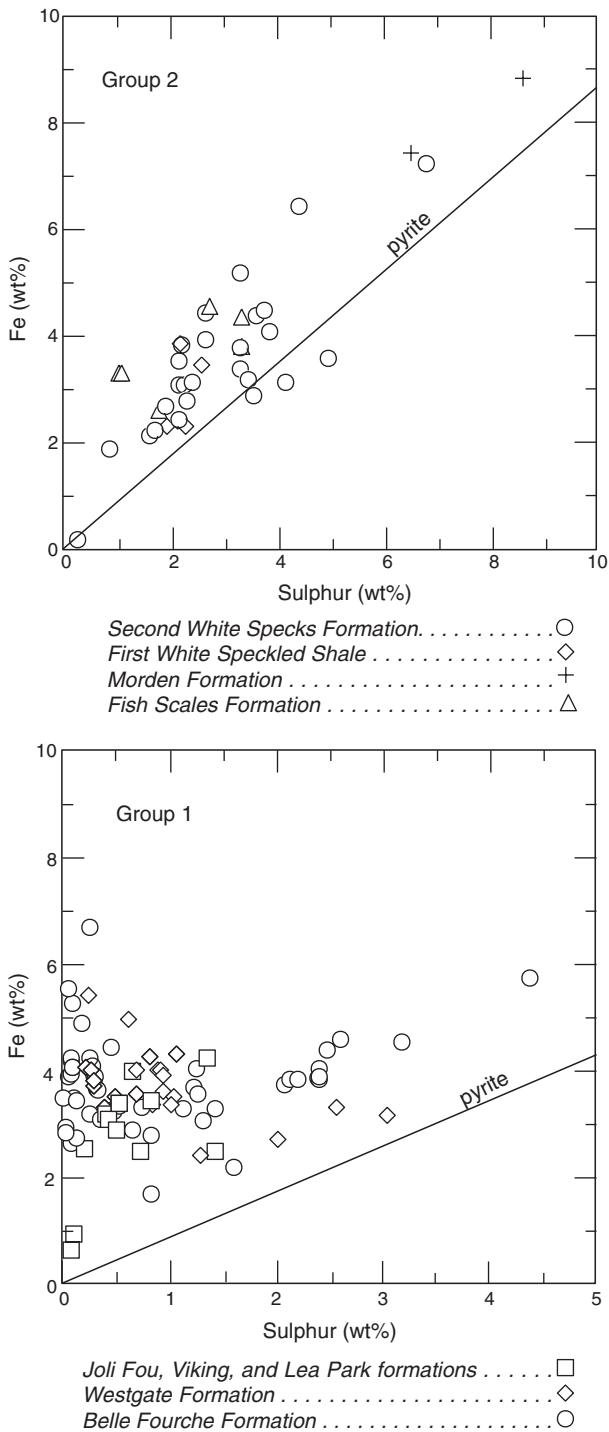

Figure 8. Sulphur and iron systematics for transgressive (Group 2) and progradational (Group 1) shales. Pyrite line is composition of stoichiometric pyrite. Note scale difference for the x-axis.

minerals present in the calcareous Second White Specks Formation and the calculated abundances are plotted against the characteristic peak intensity (Fig. 10). These results indicate that for calcite, the method works reasonably well (Fig. 10a). However, for dolomite, the correlation is poor

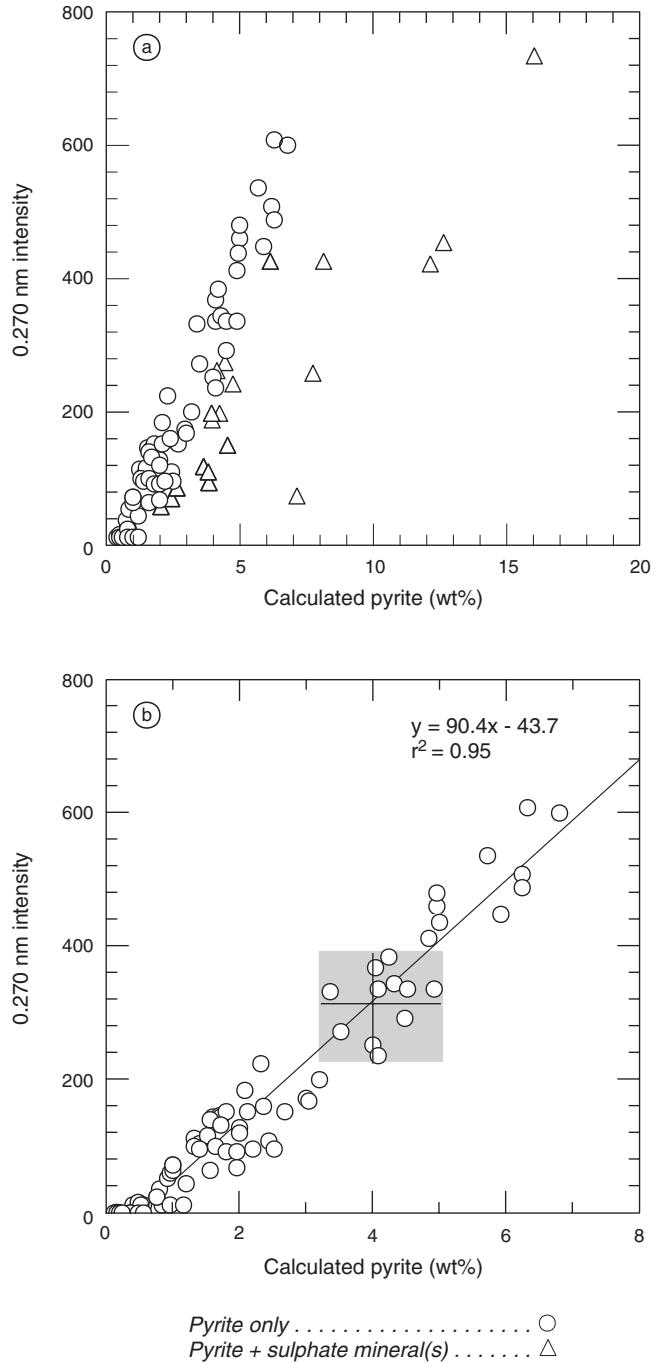

Figure 9. Characteristic peak XRD intensity versus the calculated abundance of pyrite. The presence of sulphate minerals (a) distorts the regression (b) if sulphate sulphur is assigned to pyrite. The regression in (b) is used to calculate pyrite abundances where no sulphur analyses are available.

(Fig. 10b). This is due to either the presence of small amounts of chlorite in the sample or a variable dolomite composition that includes some ankerite. Chlorite, particularly clinochlore, is susceptible to acid treatment and Mg contribution to the leachate from this clay mineral is probable. The oxide abundances must be balanced with the TIC and therefore carbonate totals should be accurate. However, in samples with multiple carbonate species and

chlorite, the calculated composition of individual species may be significantly in error.

Clay mineralogy

Standard XRD treatments of these samples (Fig. 11) indicate that this fraction is composed largely of I/S, kaolinite, quartz, and minor chlorite. In some samples, a sharp, symmetrical peak at $\sim 10\text{\AA}$ suggests the presence of well-crystallized illite or muscovite, which is confirmed by SEM (see below). Discrete illite is determined to be present by the occurrence of a series of peaks that show no change with EG-solvation and that exhibit "ideal" Bragg behavior (Fig. 12), as defined by Bailey (1982). The expandable component in the I/S is highly variable (Fig. 11, 13). Using the methods of Srodon (1980) and Moore and Reynolds (1989), estimates of the proportion of expandable component (smectite) range from < 10 to > 90 per cent, with most samples in the 70 to 90 per cent range. Estimates of expandability are hampered by the presence of detrital illite (Srodon, 1980) and comparison of the results from different methods is poor. Ordering of the I/S is predominantly random (R0). Only two samples exhibit a peak between 11 and 13 \AA with EG saturation, suggesting the presence of a superlattice peak and R1 or greater ordering (Moore and Reynolds, 1989).

Even the smallest size fractions (< 0.2 to 0.05 μm) are not monomineralic and the separation of detrital illite and the I/S is not complete (Fig. 13). In order to constrain the composition of an "end-member" smectite, bentonites from the Colorado Group were analyzed by XRF. XRD of these samples indicates that the clay component is virtually pure smectite with variable amounts of kaolinite (Fig. 14). The compositions of matrix I/S and smectite from bentonites were calculated from the XRF analyses by linear programming. The results are given in Table 6.

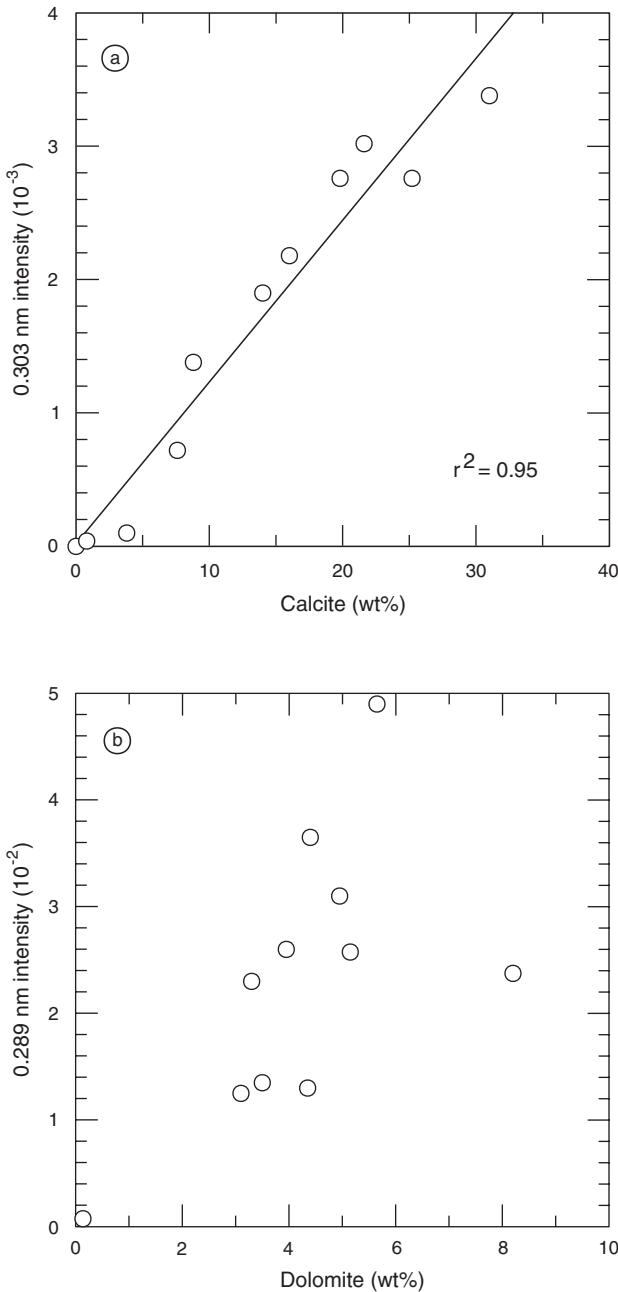

Figure 10. Characteristic XRD peak intensity versus the calculated abundances of calcite and dolomite. Calcite abundances (a) may be estimated from the 0.303 nm intensity whereas the characteristic dolomite peak (b; 0.289 nm) is unreliable.

Mixed-layer clay compositions are commonly plotted on ternary diagrams (Fig. 15) with vertices represented by the minerals celadonite, muscovite and pyrophyllite (CMP diagram). The rationale for this comes from the observation that variable cation substitutions in tetrahedral and octahedral positions are the primary replacement mechanism in micas (Yoder and Eugster, 1955) and a major control on resulting 2:1 clay mineral (and mica) compositions (Ross and Hendricks, 1945). Increasing cation substitution for Si in the tetrahedral layer results in an increased tetrahedral layer charge. Divalent cation substitution for Al in the octahedral layer results in an octahedral layer charge and it is the variable layer charges that result in the attraction of different interlayer cations and the formation of 2:1 dioctahedral clay minerals. Pyrophyllite ($\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2$) has no layer charge; muscovite ($\text{KAl}_3\text{Si}_3\text{O}_{10}(\text{OH})_2$) has only a tetrahedral layer charge; and celadonite ($\text{K}(\text{Al},\text{Fe},\text{Mg})_{2-3}\text{Si}_4\text{O}_{10}(\text{OH})_2$) has only an octahedral charge. The range of

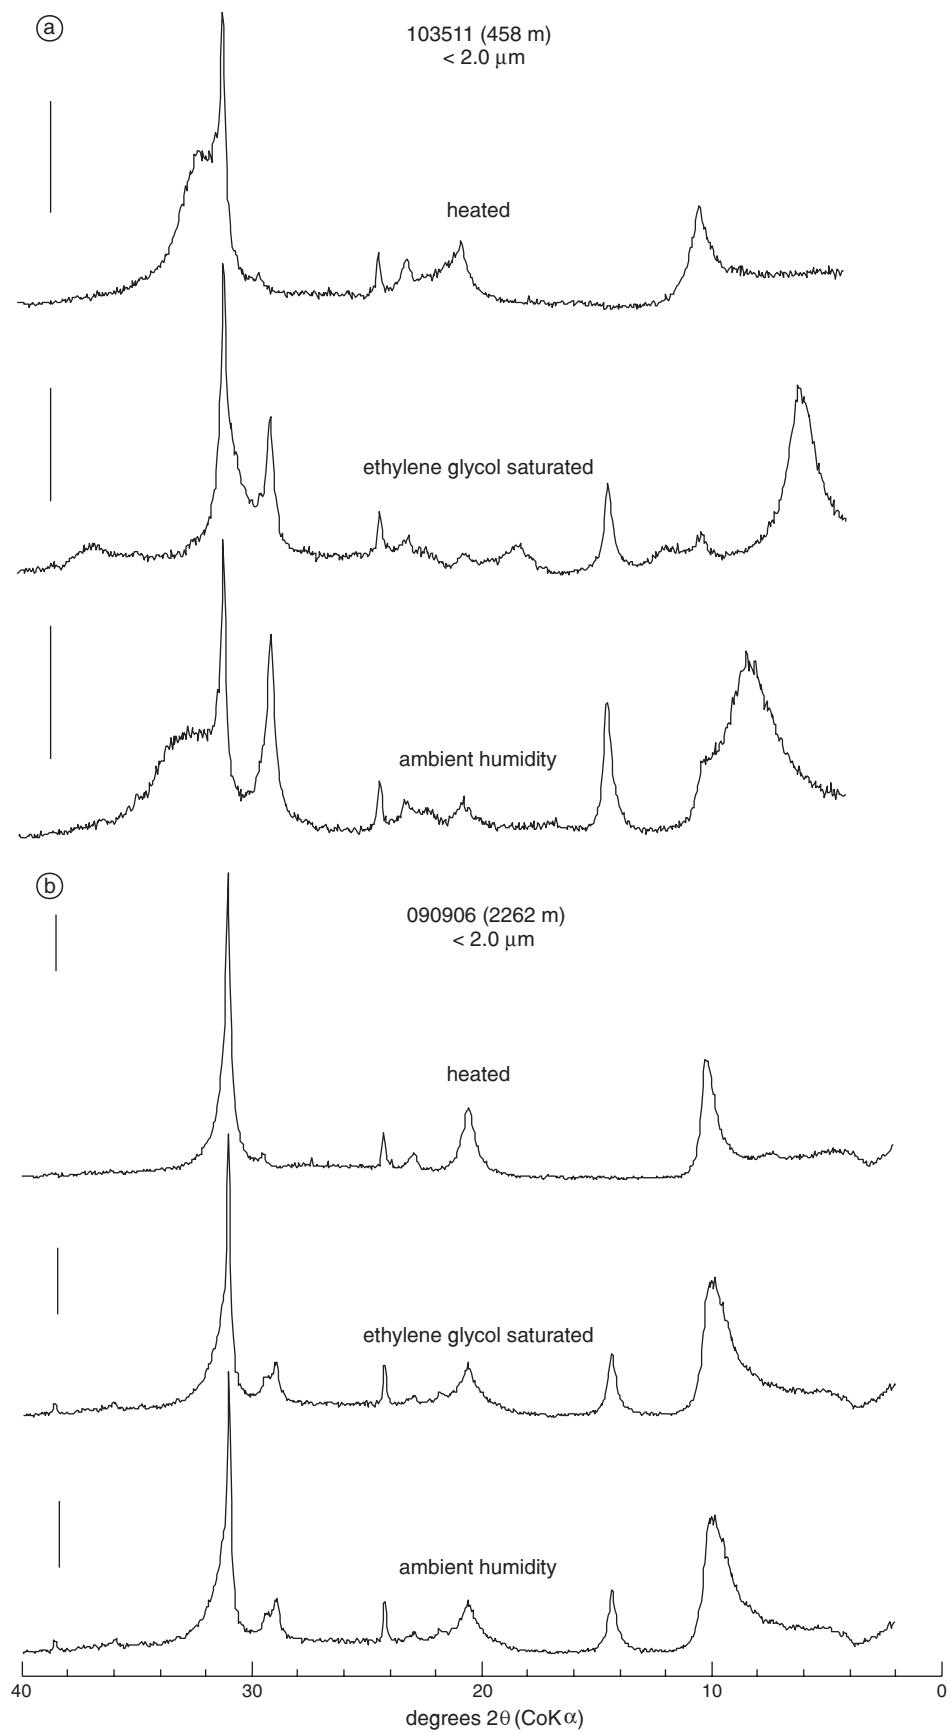

Figure 11. XRD patterns of $< 2 \mu\text{m}$ separates after standard treatments - a) sample 103511, b) sample 090906. Scale bars = 1000 cps.

chemical compositions of 2:1 dioctahedral clay minerals, including smectite, illite and mixed layer I/S, can be represented in this compositional space (Hower and Mowatt, 1966).

The compositions of Colorado Group I/S and bentonites are plotted on a CMP ternary (Fig. 15) and an element ratio plot (Fig. 16). Most smectites from bentonites show little tetrahedral substitution (Fig. 15) and therefore plot closer to the pyrophyllite end-member. There are exceptions. One smectite from each of the Westgate, Fish Scales and Belle Fourche formations falls above the 40% celadonite value indicating enrichment in Fe and/or Mg. In the case of the Westgate smectite, XRD indicates that this bentonite contains a considerable amount of siderite. The high celadonite component may reflect the Fe-rich bulk chemistry or may result from contamination by adsorbed Fe-oxides. Fe-oxides may be produced from the oxidation of reduced Fe by meteoric water or Fe oxidation during sample preparation.

In the case of the Fish Scales, the bentonite in question contains a large amount of apatite and the smectite composition is Ca-rich. The substitution of octahedral Mg or Fe^{2+} by Ca would have the effect of increasing the celadonite component on this type of diagram. The sample from the Belle Fourche Formation contains a significant amount of both apatite and siderite.

The shale matrix I/S contains a greater proportion of the muscovite component, indicating a more illitic composition compared to the bentonites. In the Westgate Formation, there

appears to be a significant increase in the celadonite component. In the Belle Fourche, a large number of samples have virtually no pyrophyllite component. Most of these Belle Fourche samples are from proximal prodeltaic deposits (Caritat et al., 1994a) in the northwest part of the study area and are also the most deeply buried. The I/S in these samples is illite-rich (Fig. 11b) and two of these samples (#062206, 540 m and #090906, 2262 m) show R1 or greater ordering.

Another way to examine the clay compositions is on a cross-plot of diagnostic element ratios (Fig. 16). This type of plot has the advantage of examining the chemical data directly without introducing the artifact of normalization to a structural formula of 22 charges, as is done on the muscovite–celadonite–pyrophyllite ternary. In addition, on an element ratio diagram, minerals plot as points and the bulk chemistry can be interpreted in terms of individual phases. The Si/Al–K/Al plot is used because: 1) Si and Al are the primary building blocks of phyllosilicates, 2) Si and K are essentially a coupled substitution in I/S, and 3) if Al is conserved in the system, mineralogical trends should be evident as the ratio of Si to K changes (Pearce, 1967).

Figure 16 indicates the low K and high Si content of the bentonite smectite. Westgate Formation matrix I/S shows higher Si whereas the Belle Fourche Formation shows lower Si with no discernible difference in K content. In the Fish Scales and Second White Specks formations, an increase in K content distinguishes the matrix I/S from the bentonite smectite. This type of diagram will be used in subsequent sections to evaluate bulk chemical compositions and diagenetic processes.

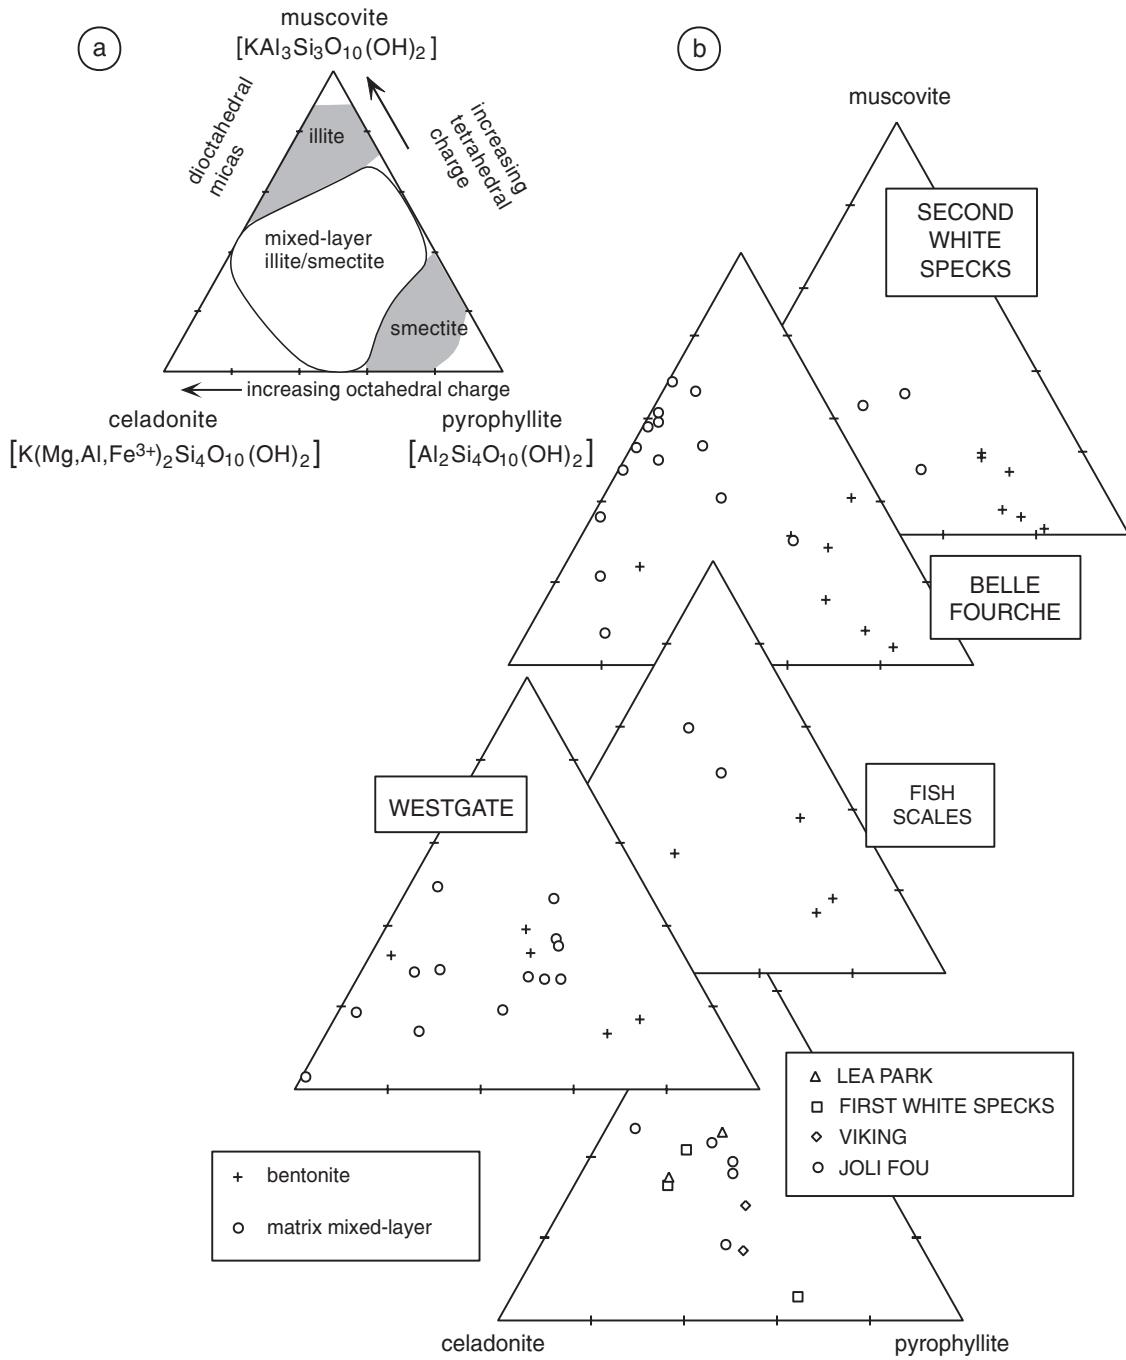

Figure 15. a) Schematic celadonite–muscovite–pyrophyllite (CMP) ternary diagram illustrating the relationship between layer charge and the compositions of illite, smectite, and mixed-layer clays (after Hower and Mowatt, 1966). b) Colorado Group shale I/S and bentonite smectite compositions for each formation on a CMP ternary.

Carbonate isotopic compositions

Carbonate isotopic data are summarized in Table 7. Three concretion types are present in Colorado Group shales: calcite, zoned siderite and unzoned siderite concretions. Calcite concretions, which occur only in the calcareous upper Belle Fourche and the Second White Specks formations, are depleted in ^{13}C and relatively enriched in

^{18}O and show little or no isotopic zoning (Fig. 17). Isotopically zoned and unzoned siderite concretions occur in the lower Belle Fourche (noncalcareous) and the Westgate formations (Table 7 and Fig. 17).

The $\delta^{18}O$ values for the calcite concretions suggest formation from basinal fluids of nearly marine oxygen isotopic composition at low temperatures. The very depleted

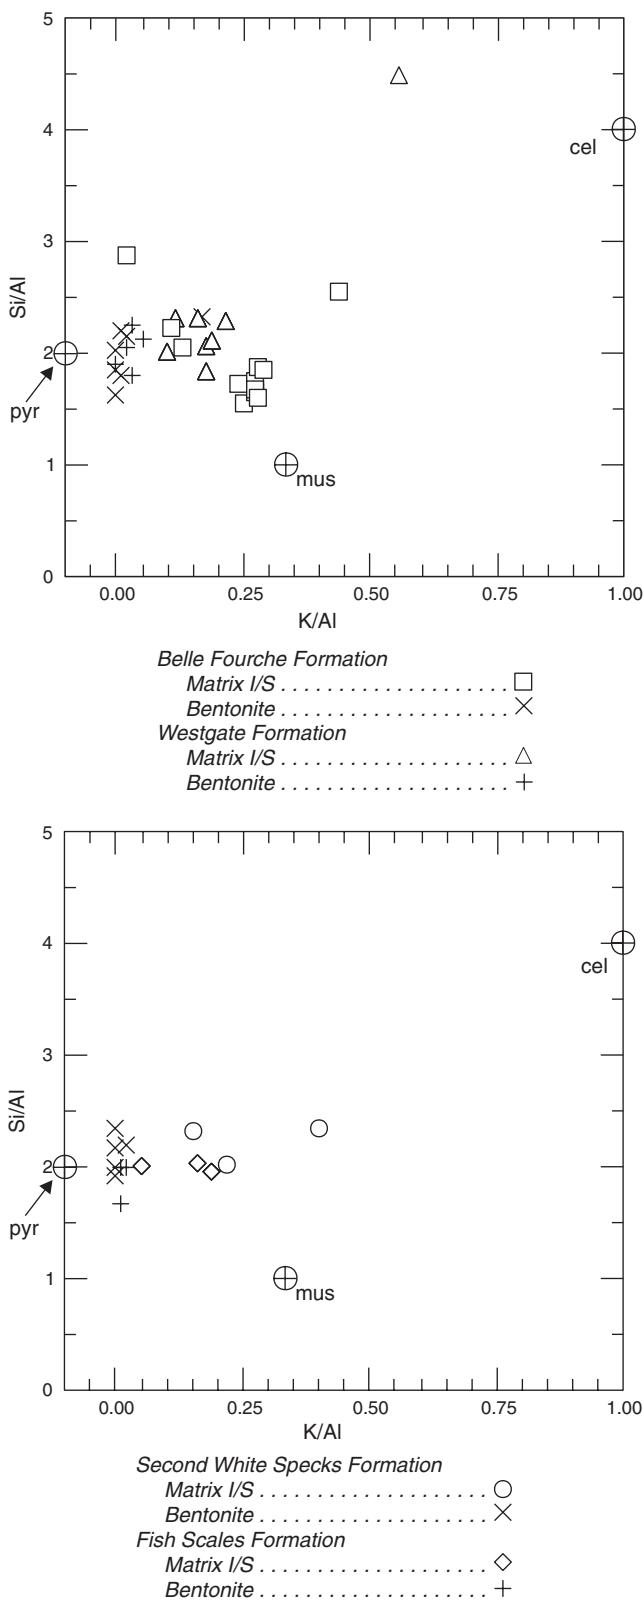

Figure 16. Shale I/S and bentonite-smectite compositions on an element ratio plot. See text for discussion.

$\delta^{13}\text{C}$ values reflect OM oxidation, and the carbon isotopic signature suggests most carbon is sourced from OM. The mechanism of OM oxidation is most likely sulphate reduction (see below). In contrast, fracture-fill calcite (Fig. 17) is enriched in $\delta^{13}\text{C}$ and depleted in $\delta^{18}\text{O}$. Paired concretion and fracture-fill calcite show a consistent difference in $\delta^{18}\text{O}$ of approximately 10.2‰.

Unzoned siderite concretions in the Belle Fourche Formation have $\delta^{13}\text{C}$ values near 0‰ PDB and $\delta^{18}\text{O}$ values between ~21 and 24‰ SMOW. Unzoned concretions in the Westgate have similar oxygen isotopic compositions but are depleted in ^{13}C (Fig. 17). Isotopically zoned concretions from the Westgate Formation show about a 3‰ depletion in $\delta^{18}\text{O}$ from the concretion center to the margin. $\delta^{13}\text{C}$ values similarly decrease, albeit more variably, from core to margin (Fig. 17). The oxygen isotopic compositions of both the zoned and unzoned siderite concretions could result from one, or a combination, of processes that include: 1) variable mixing of meteoric and marine pore waters, 2) formation from marine pore waters that have been altered isotopically by clay mineral authigenesis, and 3) formation at temperatures greater than surface temperature. Negative $\delta^{13}\text{C}$ values reflect the mixing of dissolved HCO_3^- derived from the oxidation of organic matter with marine HCO_3^- . Positive $\delta^{13}\text{C}$ values, which range up to ~7‰ PDB, indicate CO_2 from methanogenesis incorporated into concretion carbonate minerals. The nature of concretion formation is discussed further in the diagenesis section.

Sulphide sulphur isotopic composition

Sulphur isotopic data are summarized in Table 8. The extreme range of ^{34}S values is characteristic of sedimentary sulphide and the predominance of very depleted ^{34}S values indicates that bacterial sulphate reduction is the primary mechanism of sulphur incorporation into Colorado Group shales (Thode et al., 1951). A detailed discussion of the sulphur isotopic data is deferred to the section on diagenesis.

FORMATION DESCRIPTIONS

The integration of lithological, geochemical and biostratigraphic data results in the differentiation of four regionally mappable lithostratigraphic shale units that comprise the lower Colorado Group. Biostratigraphic analysis relies primarily on foraminiferal, dinoflagellate and coccolith assemblages. In addition, there are local accumulations of sandstone that interfinger conformably or disconformably with the shales. Shale descriptions and the stratigraphic nomenclature used herein were originally presented in Bloch et al. (1993) and Schröder-Adams et al.

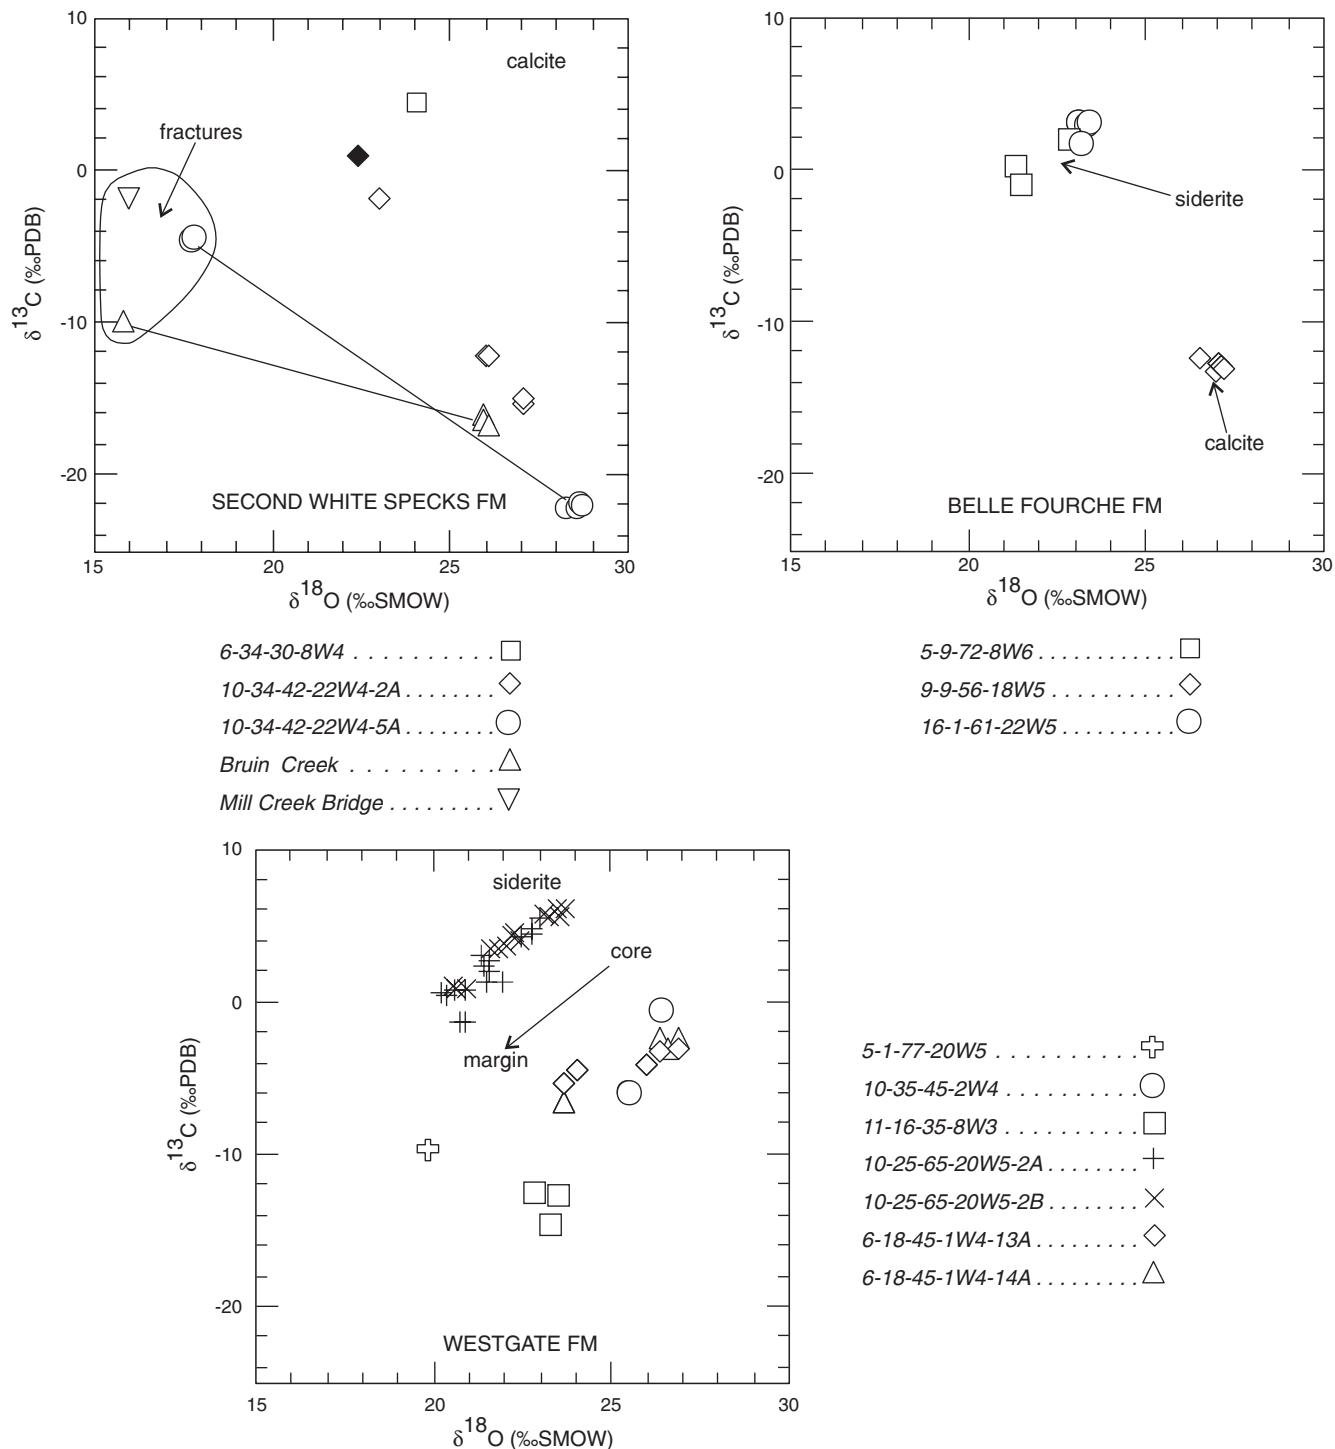

Figure 17. Carbon and oxygen isotopic composition of calcite and siderite concretions for the Second White Specks, Belle Fourche, and Westgate formations. Second White Specks Formation fracture-fill cements are circled. Lines connect fracture cements with concretion matrix of the same sample. Filled diamond is dolomite. See Table 1 and Figure 1 for outcrop locations.

(1996) and much of that data is reiterated below. Additional data on the shales (Tables 9, 10) are included in this report to provide a comprehensive description of the lower Colorado Group succession.

Westgate Formation

The Westgate Formation is a wedge of noncalcareous mudstone to siltstone that thickens from approximately 20 m

*TOC, HI abd OI by pyrolysis; Fe₂O₃ by XRF; S by combustion

on the Saskatchewan-Manitoba boundary to 120 m in northwestern Alberta. In southwestern Alberta, the Westgate Formation is less than 20 m thick and pinches out by onlap west of the 5th Meridian.

The basal contact with the underlying Viking Formation is characterized by the disappearance of sandstone and/or a noticeable decrease in siltstone and sandstone content. The wireline signature of the basal contact with the underlying Viking Formation is best expressed by a marked increase in resistivity and sonic transit time.

The Westgate Formation is characteristically heterolithic, typically comprising finely interbedded siltstone and claystone laminae. Siltstone beds are 1 to 5 cm thick, sharp-

based and locally graded. The basal Westgate Formation is commonly finely laminated with minimal bioturbation. Bioturbation increases upsection, becoming moderate to intense near the top of the formation. Identifiable trace fossils include *Planolites*, *Chondrites*, *Terebellina*, and *Helminthopsis*. Resistivity, density, and gamma-ray responses as well as composition of the Westgate Formation are relatively uniform throughout (see Bloch et al., 1993, fig. 8; Table 9).

Detrital grains are primarily silt-sized quartz and K-feldspar (Plates 1c, 3e, 4d-f) with subordinate, plagioclase feldspar (Plates 1d, 2a), muscovite (Plate 3f), biotite (Plate 1b, d), apatite – primarily as bioclasts (Plate 4c), oxides of Ti (Plate 5f), and chamosite (Plate 1f). Other

Abbreviations: Pyr = pyrite, Jar = jarosite, Alu = alunite, Cal = calcite, Sid = siderite, Dol = dolomite, Gyp = gypsum, Apa = apatite, Ana = anatase, Qtz = quartz, I/S = mixed-layer illite/smectite, Kao = kaolinite, Ksp = K-feldspar, Plg = plagioclase feldspar, TOC = total organic carbon (from Rock-Eval)

Low totals indicate presence of some amorphous material, primarily iron oxides and hydroxides, but may also result from errors associated with clay mineral compositions, particularly I/S

¹I/S includes trace amounts of muscovite, as determined by BSEM, and discrete illite, as determined from XRD characteristics

*contains Ca- zeolite, most likely heulandite or mordenite

**contains 15–20 wt% heulandite, not reflected in total

detrital clasts include argillaceous rock fragments (Plate 1e) and volcanic clasts (Plate 2a–c). Rare detrital grains are medium sand-sized (Plate 1d). The rock fabric is characterized as matrix supported (Plate 1b), but silt laminae may be framework supported (Plate 1c). Calculated mineral abundances are shown in Table 9.

Authigenic silicate minerals include quartz (Plate 2e), I/S (Plate 3a, b), kaolinite (Plate 3d–f), and glauconite (Plate 4a, b). Authigenic frambooidal pyrite is ubiquitous (Plate 5a–f) but heterogeneously distributed (Plate 5a, b). The highest concentrations of pyrite are associated with organic-rich laminae. Pyrite occurs as frambooids, zoned aggregates, and as pseudomorphs of feldspars, micas (Plate 5c), and bioclastic debris (Plate 5e). Siderite occurs dominantly as concretions up to 1 m thick. In bioturbated samples, authigenic siderite is abundant in the matrix (Plate 6a–f) and the fabric of the rock is noticeably homogeneous (Plate 2e). Minor authigenic calcite is also present (Plate 6d).

Feldspar dissolution is a common texture (Plates 2d, 6a) and much of the kaolinite occurs as pseudomorphic replacement of K-feldspar or plagioclase (Plate 3c–e). Plagioclase feldspar appears more susceptible to dissolution than K-feldspar (Plate 2d). Biotite and muscovite are also replaced by kaolinite (Plates 1b, 4b).

The total organic carbon (TOC) content averages 1.8 wt% (range 1.1–3.3 wt%) and is mainly terrestrially derived Type III OM (Fig. 4). The sulphur content averages about 0.9 wt% (range 0.2–3.0 wt%). The carbon/sulphur values vary from < 0.5 to ~8.5 with a mean of 2.7 (Table 3, Fig. 7). High TOC (3.0 wt%), sulphur abundances (3.0 wt%), and HI

values (> 200 mgHC/gOC) occur near the base of the Westgate Formation in some cores (e.g., 10-25-65-20W5, 10-5-53-20W5).

Fish Scales Formation

The Fish Scales Formation is a finely laminated, non-calcareous claystone to mudstone, generally less than 20 m thick. In the central Foothills of Alberta the Fish Scales Formation contains a thin sandstone up to 3.5 m thick (Fish Scales Sandstone; Wall and Germundson, 1963) and capped with chert pebbles. In central Saskatchewan, the Fish Scales Formation is difficult to distinguish but may be recognized by the occurrence of a thin (< 5 cm), coarse grained sandstone or pebble layer, overlain by organic-rich shale. This coarse grained, basal layer contains bioclastic debris composed largely of phosphatic skeletal vertebrate remains, belemnites, and other phosphatized bioclastic debris. The base of this unit is typically sharp and may be overlain by parallel-laminated or ripple crosslaminated sandstone (Leckie et al., 1992). In southwestern Alberta, the Barons sandstone unconformably overlies the Fish Scales Formation and locally may remove Fish Scales shales westward toward outcrop in the Rocky Mountain Foothills. South of Township 25 and west of the 5th Meridian, the Fish Scales Formation, like the Westgate Formation, is not present.

The wireline expression of the contact between the Westgate Formation and the Fish Scales Formation (commonly referred to as the "Base of Fish Scales") is a sharp increase in the gamma-ray and resistivity responses and an abrupt, but lower magnitude decrease in sonic transit

Table 10

Bentonite mineralogy calculated from bulk XRF data

Smc = smectite, Kao = kaolinite, Alb = albite, Ano = anorthite, Ksp = K-feldspar, Qtz = quartz, III = illite, Chl = chlorite, Ann = annite, Phg = phlogopite, Bte = biotite, Anl = analcime, Ana = anatase, Apa = apatite, Pyr = pyrite, Jar = jarosite, Sid = siderite, Cal = calcite

*illite composition is $K_{.71}Mg_{.61}Al_{2.01}Si_{3.51}$ per 10 oxygens

#siderite composition is $Fe_{.87}Mg_{.12}Mn_{.01}CO_3$

+siderite composition is $Fe_{.85}Mg_{.13}Mn_{.02}CO_3$

time and formation density. Within the Fish Scales Formation, log responses are variable, reflecting a heterogeneous lithology that includes numerous bentonites, the presence of well developed Barons Sandstone lenses in southwestern Alberta, and variable organic-matter content.

Fish remains and algal cysts dominated by *Lanceolatta lancetopsis* are abundant. Bioturbation is sparse to nonexistent. Bentonites are common, range in thickness from < 1 to about 30 cm, and increase in abundance to the southwest. Some bentonites are graded and contain biotite and feldspar (sanidine?) crystals. Buff to black phosphatic beds up to 5 cm thick also may be present.

The silicate mineralogy of the Fish Scales Formation is similar to that of the Westgate Formation (Table 9) but the silt fraction is noticeably finer grained (Plate 7a-d). Silt grains larger than 20 μm are rare. The detrital silt-sized material is dominantly quartz with K-feldspar (Plate 7d), plagioclase feldspar (Plate 7c), micas and a suite of accessory minerals similar to that of the Westgate Formation. The silt- and sand-sized fractions are made up of quartz (29–60 wt%) and potassium feldspar (7–13 wt%). Clay minerals include I/S (8–20 wt %), kaolinite (4–20 wt%), and illite (4–12 wt %), with minor chlorite. Pyrite is more abundant than in the Westgate Formation (up to 6.2 wt%) and is dominantly frambooidal in habit (Plate 7 e, f). Dolomite is common in abundances less than 5 wt%. Siderite is rare but, where present, contains detectable amounts of Mn (Plate 7c).

TOC values within the Fish Scales Formation average 3.2 wt% (range, 1.8–8.0 wt%) with HI values from approximately 50 to 440 mgHC/gOC. Low TOC and HI values (Fig. 4, 7) are generally restricted to the northwest (e.g., 5-1-77-20W5) but locally bioturbated zones also show lower HI values. The mean sulphur content is 2.2 wt% (range, 1.0–3.4 wt%). Carbon/sulphur values vary from 0.8 to 2.0 with a mean of 1.5 (Fig. 7).

Belle Fourche Formation

The Belle Fourche Formation is a westward-thickening wedge of noncalcareous to slightly calcareous mudstone and siltstone. The minimum thickness is about 20 m in eastern Saskatchewan, and increases to over 150 m in the Foothills of northwestern Alberta. In southwestern Alberta, the Belle Fourche Formation is tabular, about 50 m thick, and contains intervals up to 10 m thick of well-developed, sharp-based lenses of Barons Sandstone. Near the 5th Meridian, south of Township 25, the Barons Sandstone unconformably overlies the Fish Scales Formation and in some places the Westgate Formation, indicating that the lowermost strata of the Belle Fourche Formation in this area may be erosionally truncated.

Where the Fish Scales Formation is present, its contact with the Belle Fourche is transitional and commonly contains numerous thin bentonites. The transition is indicated by the first occurrence of calcareous sediment, the presence of Inoceramids, or a noticeable increase in bioturbation. In some cases, no change in sediment composition or texture is observed and the basal Belle Fourche may only be differentiated from the underlying Fish Scales Formation by a change in organic matter type and abundance, or the occurrence of rare, agglutinated foraminifera (see below).

The wireline expression of this contact is manifested as an abrupt increase in sonic transit time and formation density. Resistivity and gamma-ray signatures are variable and may mimic those of the Fish Scales Formation. Within the Belle Fourche, the gamma-ray response generally declines upsection, and is accompanied by an increase in sonic velocity and formation density (see Bloch et al., 1993, fig. 8).

Bioturbation in most of the Belle Fourche is sparse to moderate, with *Planolites* and *Chondrites* the only observed traces. Siltstone beds are sharp based, erosive and may be graded. Parallel laminae and combined-flow ripples are common.

In the western Interior Plains (e.g., 5-9-72-8W6), coarsening-upward cycles up to 20 m thick, comprising coarse silt to medium sand, are present in the middle and upper sections of the Belle Fourche Formation. These cycles thicken to the west-northwest and contain abundant sideritic concretionary horizons. Bioturbation within these cycles varies from moderate to intense, and *Gordia*, *Helminthopsis*, *Teichichnus*, *Planolites*, and *Chondrites* are present. In comparison, to the south and east, the equivalent of this cyclic interval consists of thin (< 5 cm), erosive and sharp-based sand or silt beds. Beds composed of bioclastic macrofossil debris also are present.

The mineralogy of the Belle Fourche Formation is similar to that of the Westgate Formation (Table 9) but minor amounts of dolomite may be present, particularly in the upper part of the section. Quartz (28–74 wt%) and potassium feldspar (1–11 wt%) are the major silt-sized mineral constituents and the silt fraction is noticeably coarser than that of the underlying Fish Scales Formation (Plate 8a, b, d, e). The clay minerals are dominantly kaolinite (7–40 wt%) and I/S (3–17 wt%). Siderite averages 2.4 wt% (range 0–4.5 wt%). Pyrite occurs as frambooids and aggregates in abundances from < 0.1 to 5.9 wt%. Calcareous bioclasts are more common in the upper Belle Fourche (Plate 8c, f). Large, detrital micas are locally common (Plate 8a, b, d, e). Authigenic minerals include pyrite, siderite, and kaolinite (Plate 8c, e).

Belle Fourche TOC abundances average 1.7 wt% (range, 0.4–2.7 wt%) with relatively low HI values ($m=104$ mgHC/gOC). The sulphur content is from < 0.1 to 3.2 wt%, averaging 1.2 wt%; carbon/sulphur values are variable (~1–27; mean = 5.5) and poorly correlated (Fig. 7). This reflects the wide range of mixing of Types II and III OM and the extremely variable sulfur content (expressed as pyrite and sulfate minerals in Table 9) within the Belle Fourche Formation (Fig. 4).

Second White Specks Formation

The Second White Specks Formation is a limestone to marlstone in Saskatchewan, a calcareous claystone to siltstone in eastern and southern Alberta, and grades to a calcareous siltstone in northwest Alberta. This unit thickens from about 25 m at the Saskatchewan–Manitoba boundary (Williams and Bayliss, 1988) to over 90 m in the Peace River Arch area of northwestern Alberta (Stelck and Wall, 1954). The thickness of the Second White Specks Formation (SWS) is generally less than 20 m in southern Alberta, but reaches up to 55 m in southeast Alberta. The base of the Second White Specks is generally distinct and defined by an abrupt change to a very calcareous matrix. This change in lithology is typically marked by a bed of coarse bioclastic, calcareous debris 1 to 5 cm thick (Plate 9e). A bentonite bed up to 20 cm thick is typically associated with this basal bioclastic bed over much of Alberta. A calcite concretionary layer up to 30 cm thick commonly occurs in association with the bentonite.

On wireline logs, the contact between the Belle Fourche and the Second White Specks formations is expressed by an increase in resistivity and radioactivity. The gamma ray response is more variable compared to that of the Belle Fourche Formation, reflecting the greater number of bentonites. The upper contact of the Second White Specks Formation is characterized by a decrease in resistivity and sonic velocity. The overlying, noncalcareous shale also has a more uniform gamma-ray response.

Bioturbation is absent to sparse and sediments are well laminated. In the west and northwest of the study area, siltstone beds contain parallel laminae and rare, current or combined-flow ripples. The Second White Specks Formation is distinctively fissile in core and weathers to a blocky, silvery grey in outcrop. Calcite concretions up to 20 cm thick are common and generally disk shaped. The speckled nature of this unit is due to the abundance of millimetre- (or smaller) sized fecal pellets composed of calcareous coccolithic debris (Plate 9c). Other bioclasts include benthic and planktonic foraminifers (Plate 9b), pelecypod fragments, fish scales and bones (Plate 9d), ammonites, whole shells, shell fragments, Inoceramid prisms (Plate 9d, e), and algal cysts. Inoceramid debris is

particularly abundant in the Second White Specks Formation. The calcareous nature of this formation is due mainly to the abundance of this bioclastic material.

The mineralogy of the Second White Specks Formation is markedly different than that of the underlying shales (Table 9) because of the variable, dominantly bioclastic, carbonate content (0–88 wt%). In addition, dolomite (1.5–6.3 wt%) and frambooidal pyrite (0.0–7.0 wt%) are relatively abundant. Pyrite occurs almost exclusively as disseminated frambooids (Plate 9a, b). Siderite is rare. The silicate mineralogy includes quartz (2–52 wt%), I/S (5–48 wt%), kaolinite (2–25 wt%), potassium feldspar (0–5 wt%), and plagioclase (< 3 wt%), with minor to trace amounts of biotite, muscovite, and chlorite (Plate 9f, Table 6). Clay-sized quartz is abundant (Plate 9f). Authigenic kaolinite fills foraminiferal tests (Plate 9b) and trace amounts of glauconite may be present. Authigenic jarosite, gypsum, and anhydrite occur as cement in horizontal microfractures (Plate 9a), locally constituting up to about 13 wt%.

The mean TOC content is 5.1 wt% (range, 2–12 wt%) with HI values generally greater than 200 mgHC/gOC (Fig. 3, 10). Second White Specks Formation samples with low TOC and HI values (2–4 wt% TOC and HI < 300 mgHC/gOC) are commonly found in northwestern Alberta. The sulphur content averages 2.7 wt% (range, 0.8–4.5 wt%) and shows a crude correlation with TOC content (Fig. 7). Carbon/sulphur values vary from ~0.5 to 2.2 with a mean of 2.2.

STRATIGRAPHY AND AGE

Stratigraphic correlations and the relative ages of the studied formations are determined primarily by foraminiferal assemblages (Fig. 18, 19, Appendix B). Dinoflagellate assemblages are also utilized, particularly where sediments are barren of foraminifers. In latest Cenomanian- to Turonian-aged formations, coccoliths may also provide useful stratigraphic information. As previously indicated, foraminiferal biostratigraphy is well developed for the Cretaceous of the WCSB and the studied interval contains three foraminiferal zones. The Upper Albian *Miliammina manitobensis* Zone is present in the Westgate Formation. A detailed biostratigraphic correlation of this zone is provided by Stelck (1975). The Fish Scales Formation is barren of foraminifers and the determination of a Cenomanian age for this formation relies on the dinoflagellate assemblage (Singh 1983; Bloch et al., 1993) and its stratigraphic position (Leckie et al., 1992).

The *Verneuilinoides perplexus* Zone, of middle to Late Cenomanian age, is present in the Belle Fourche Formation. The *Hedbergella loetterlei* Zone occurs in the Second White Specks Formation, deposited during latest Cenomanian to

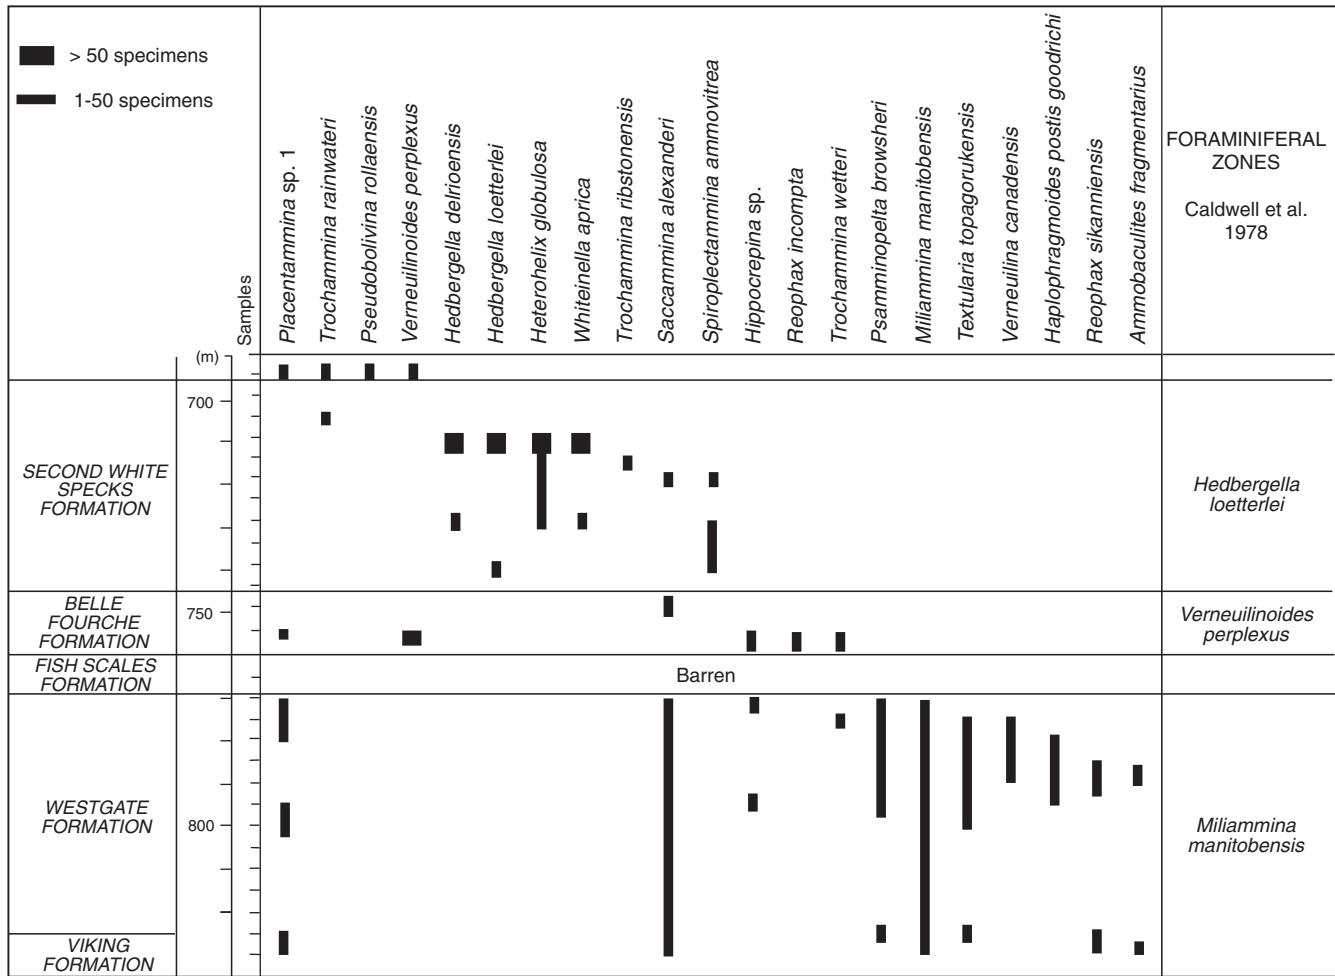

Figure 18. Biostratigraphic ranges of foraminiferal species with common occurrences at 6-34-30-8W4 in southeastern Alberta. Primitive agglutinated taxa such as *Placentammina* sp. 1 and *Saccammina alexanderi* range through several formations, but disappear in the Fish Scales Formation. The assemblage contains numerous rare species not shown in this figure (see Appendix B).

Middle Turonian time. In eastern Saskatchewan, this zone is divided into the *Clavihedbergella simplex* and *Whiteinella aprica* subzones. The base of the *C. simplex* Subzone is placed in the Upper Cenomanian, based on bivalve occurrences (McNeil and Caldwell, 1981), whereas Caldwell et al. (1978) originally had placed it in the Lower Turonian.

Absolute ages for the formations are derived from radiometric age data, primarily sanidine Ar⁴⁰/Ar³⁹ ages, of Obradovich (1991), Cobban et al. (1994) and Kowallis et al. (1995) (Fig. 20). These data have been used to calibrate the macrofossil zones of the Western Interior (Cobban and Reeside, 1962) and provide a direct correlation to the foraminiferal zonations of Western Canada (Caldwell et al., 1978). The presence of *Collignonceras woollgari* (Mantell) at 14-29-11-28W4 (2508.8m) supports a Middle Turonian age for upper Second White Specks Formation (R. Hall, pers. comm.). Sanidine (K-feldspar) is noticeably absent

from sampled bentonites in lower Colorado group shales (Table 10). This fact has to date prevented accurate age determinations from these shales.

The status of the Albian–Cenomanian boundary is confused. Recently, the *Neogastropites* fauna has been moved from the latest Albian to the earliest Cenomanian (Cobban and Kennedy, 1989; Obradovich, 1993; Cobban et al., 1994) which makes the age of the boundary considerably older (Fig. 20). However, in Canada near Fort St. John, the entire *Neogastropites* fauna, with the exception of the uppermost ammonite zone *N. maclearni*, is found in sediments that contain the assemblages of the *Milliammina manitobensis* zone (Wall, 1967; Warren and Stelck, 1969), long recognized as latest Albian in age. At the same location, the Albian–Cenomanian boundary, which has been defined as the base of the Fish Scales Formation, falls between occurrences of *N. maclearni* (Reeside and Cobban) and *N. americanus* (Reeside and Weymouth) (Stelck and

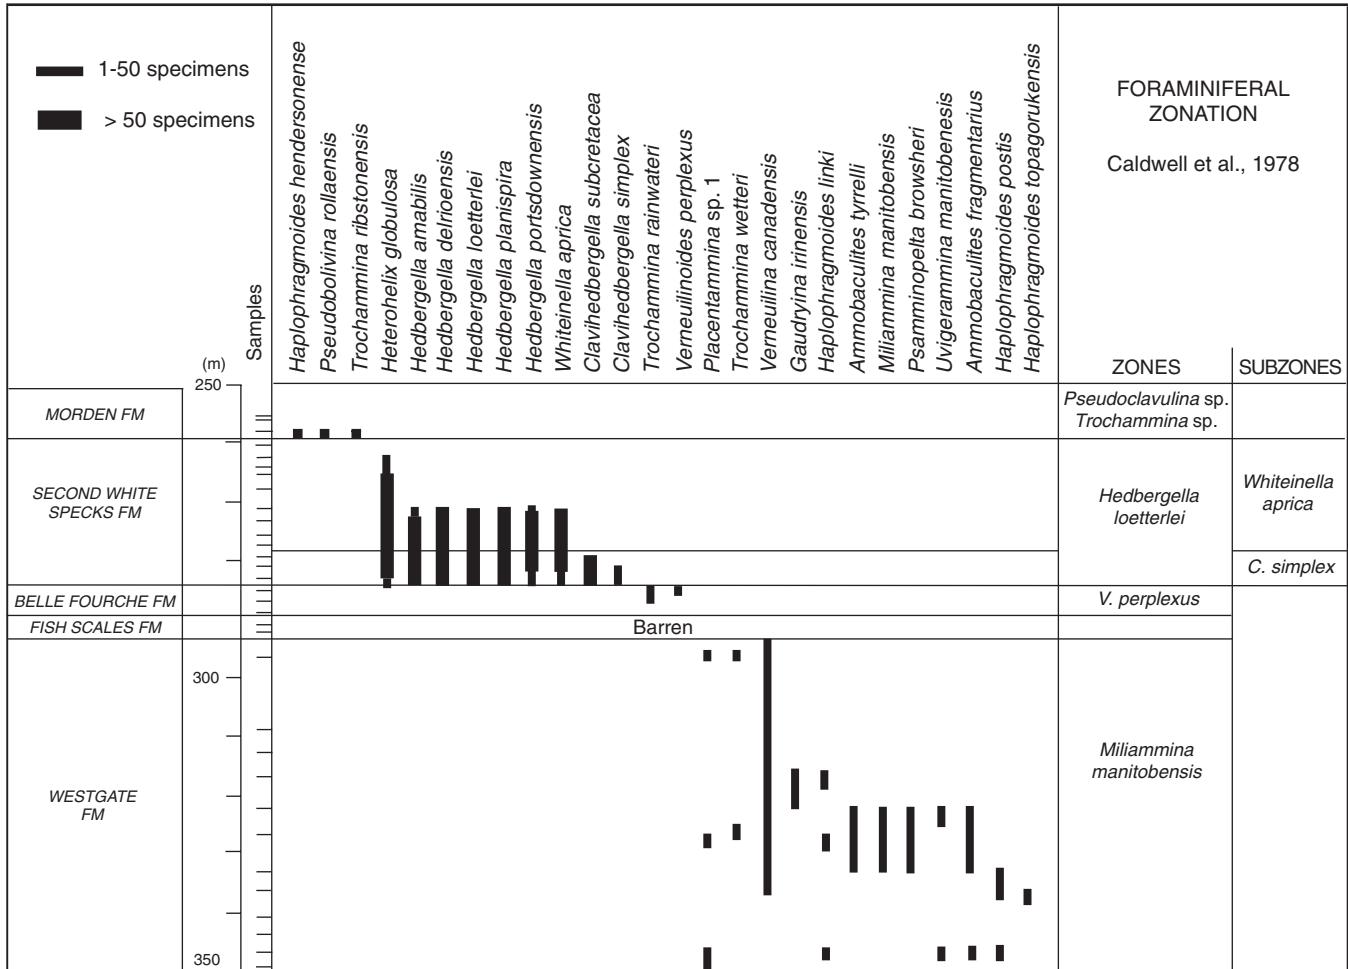

Figure 19. Biostratigraphic ranges of foraminiferal species with common occurrences at 11-36-22-1W2 in eastern Saskatchewan. All species of the Upper Albian Westgate Formation disappear at the contact with the Fish Scales Formation. All planktic species except *Heterohelix globulosa* disappear in the middle of the Second White Specks Formation, showing that the biofacies boundary is not coincident with the lithofacies boundary. This is the only location where the *Clavihedbergella simplex* Subzone could be recognized. The assemblage contains numerous rare species not shown in this figure (see Appendix B).

Armstrong, 1981). Herein, we consider the position of *N. maclearni* to be of earliest Cenomanian age, which leaves the remaining Neogastropites species in the latest Albian (see also discussion by Leckie et al., 1992).

Westgate Formation

The foraminiferal assemblage of the Westgate Formation consists of agglutinated taxa (Fig. 18, 19). Total abundance of specimens and species diversity vary significantly throughout the formation and between wells (Fig. 21, Appendix B). Faunal preservation is moderate, and includes a high percentage of severely deformed specimens, which allows, in many cases, identification only on a generic level. The assemblage contains common species such as *Bathysiphon brosgei* Tappan, *Saccammina alexanderi*

(Loeblich and Tappan), *Placentammina* sp., *Miliammina manitobensis* Wickenden, *Psamminopelta bowsheri* Tappan, *Reophax tundraensis* Chamney, *Reophax minuta* Tappan, *Reophax sikanniensis* Stelck, *Haplophragmoides postis goodrichi* Sutherland and Stelck, *Haplophragmoides gilberti* Eicher, *Haplophragmoides linki* Nauss, *Haplophragmoides hendersonense* Stelck and Wall, *Ammobaculites fragmentarius* Cushman, *Verneuilinina canadensis* Cushman, *Verneuilinoides borealis* Tappan, *Gaudryina irenensis* Stelck and Wall, *Textularia topagorukensis* Tappan, *Trochammina rutherfordi* Stelck and Wall, and *Trochammina* spp. (Plate 10). This species composition is typical for the *Miliammina manitobensis* Zone of Late Albian age (Caldwell et al., 1978). In the Rocky Mountain Foothills of northeastern British Columbia, this zone is divided into three subzones of which only the lowest, the *Verneuilinina canadensis* Subzone, can be recognized

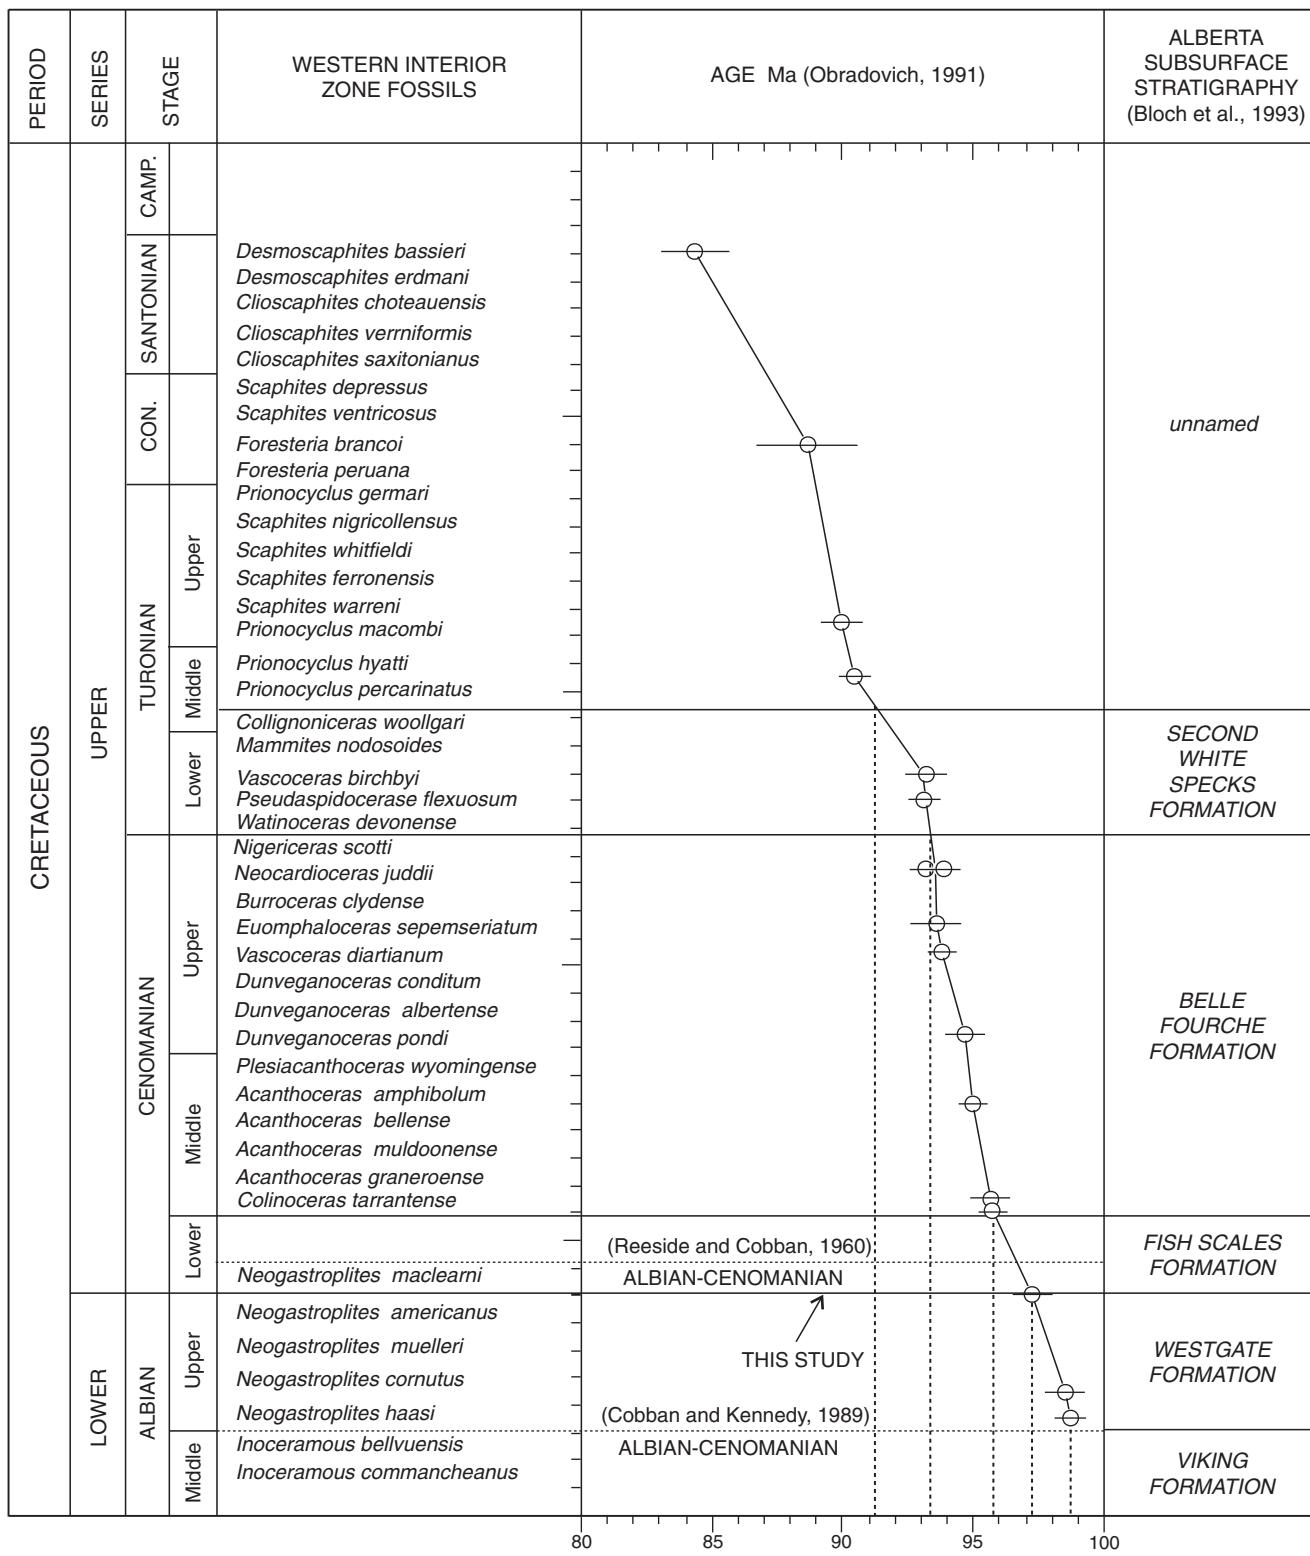

Figure 20. Macrofossil zones of the Western Interior and $^{40}\text{Ar}/^{39}\text{Ar}$ ages (modified from Obradovich, 1991) showing the estimated ages of the lower Colorado Group formations. Estimated ages for the Cenomanian-Turonian boundary range from 93.3 ± 0.2 (Obradovich, 1993) to 93.1 ± 0.3 Ma (Kowallis et al., 1995). Refer to text for the assignment of the Albian-Cenomanian boundary.

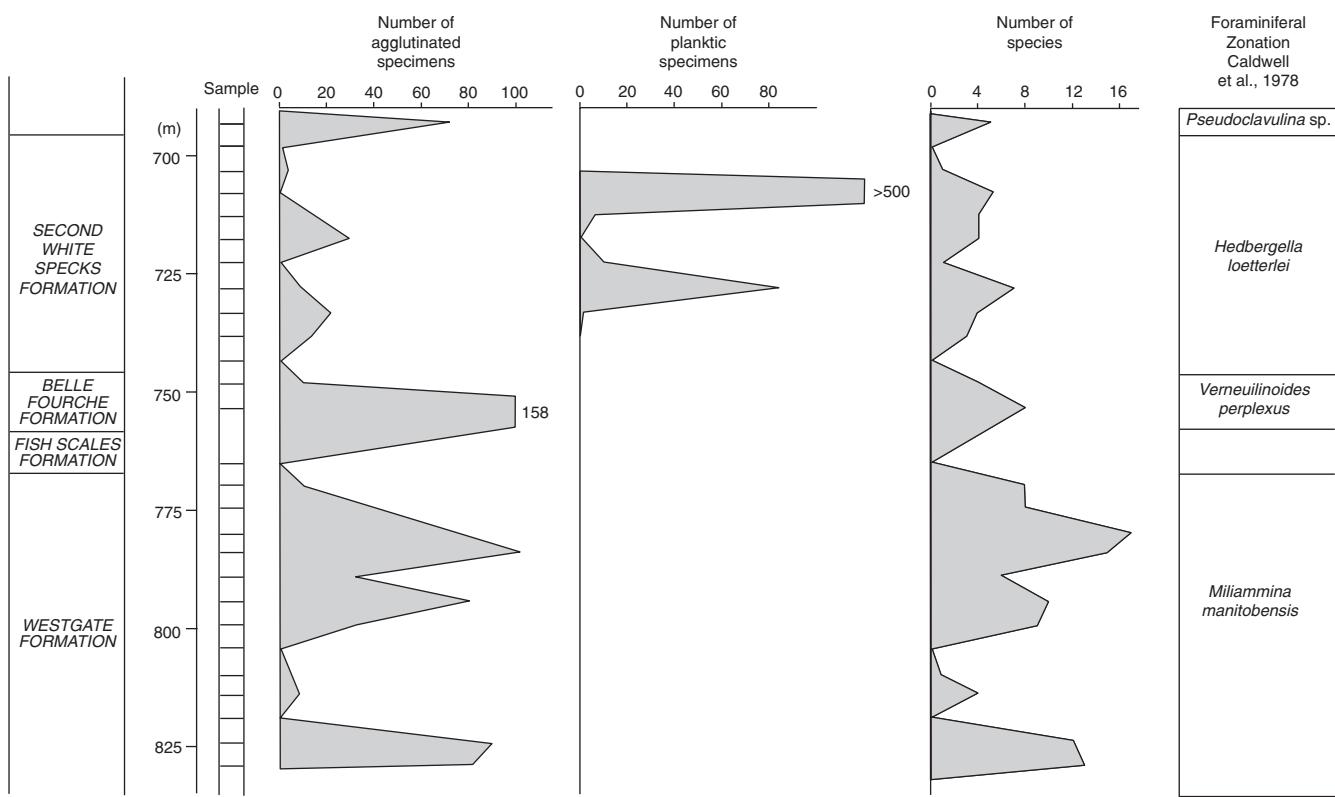

Figure 21. Total number of agglutinated and planktic foraminiferal specimens and number of species per sample at 6-34-30-8W4. Note that agglutinated foraminifera persist throughout the Second White Specks Formation at this locality.

across the plains of Alberta and Saskatchewan (Caldwell et al., 1978). In the studied sections of the Westgate Formation, no distinct faunal change is observed that would imply a regionally valid subzonation. All foraminifers disappear at the top of the Westgate Formation.

Dinoflagellate assemblages of the Westgate Formation are similar to those described by Brideaux (1971) and Singh (1971) from the correlative lower Shaftesbury Formation. Although assemblages of dinoflagellates are typically rich and varied in the Westgate, the abundance of species and specimens varies considerably. Preservation is excellent in eastern Alberta but is poor to the west, especially in Foothills sections, where increased thermal alteration causes problems in identification. Species that occur commonly in the Late Albian Westgate Formation are *Luxadinium propatulum* Brideaux and McIntyre, *Chichaouadinium vestitum* (Brideaux) Bujak and Davies, *Ovoidinium verrucosum* (Cookson and Hughes) Davey, *Cribroperidinium intricatum* Davey, *Oligosphaeridium totum* Brideaux, *Pseudoceratium expolitum* Brideaux, *Florentinia cooksoniae* (Singh) Duxbury, *Fromea fragilis* (Cookson and Eisenack) Stover and Evitt, and *Palaeoperidinium cretaceum* Pocock emend Davey (Fig. 22, 23). The above species also occur in the Cenomanian. *Luxadinium propatulum* and *Ovoidinium verrucosum* first appear in the Late Albian whereas the others have earlier first appearances. Other species in the

Westgate Formation having Late Albian first appearances are *Catastomocystis spinosa* Singh, *Ascostomocystis gigantea* Singh, *Florentinia verdieri* Singh, *Bourkidinium psilatum* Singh and *Ginginodinium evitti* Singh. The following species last appear in the Westgate: *Discorsia nanna* (Davey) Duxbury, *Microdinium opacum* Brideaux, *Protoellipsodinium spinocristatum* Davey and Verdier, *Senoniasphaera microreticulata* Brideaux and McIntyre, *Wigginsiella grandstandica* Lucas-Clark (Fig. 22). At present, a zonal scheme for dinoflagellates within the Westgate Formation cannot be determined because of the absence of distinct floral changes.

Fish Scales Formation

The Fish Scales Formation and equivalent strata are barren of foraminifers (Fig. 18, 19). Stratigraphic correlations and age must rely on dinoflagellate assemblages and stratigraphic position. No new dinoflagellate species typify the Fish Scales Formation in the study area since most species range from the Late Albian into the Cenomanian. The Fish Scales Formation assemblage is diverse, but is strongly dominated by *Ovoidinium verrucosum*, *Pseudoceratium expolitum*, *Cribroperidinium intricatum*, and *Cyclonephelium vannophorum*.

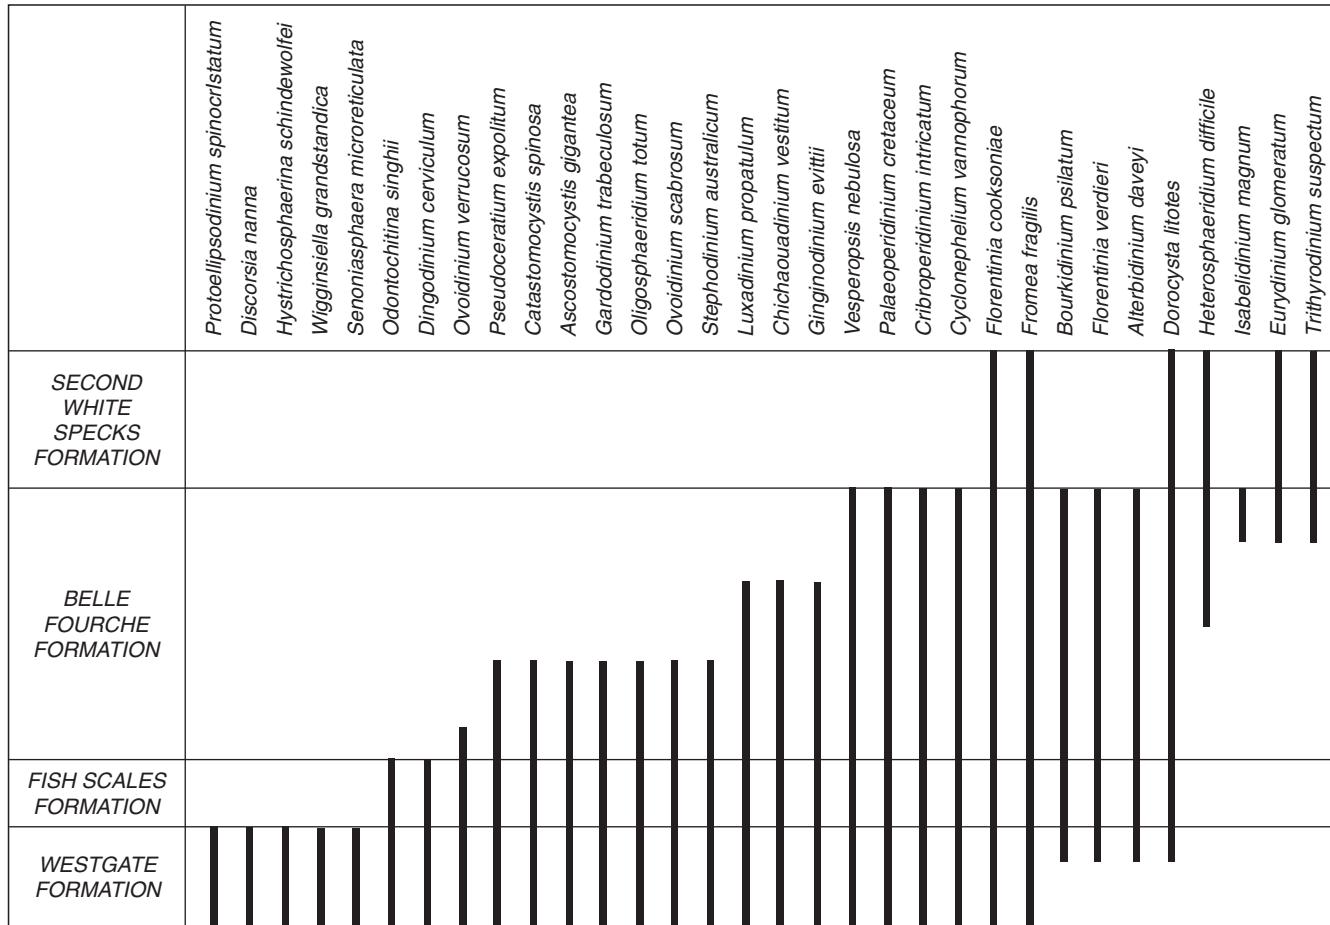

Figure 22. Dinoflagellate ranges in southwestern Alberta.

The Early Cenomanian age of the Fish Scales Formation is based on dinoflagellates from assemblages in northern Alberta, where a distinct floral change is observed between the Westgate and Fish Scales formations (Singh, 1983; Leckie et al., 1992). The transition to the overlying Belle Fourche Formation is gradational and is marked by the appearance of rare, agglutinated foraminifers of Late Cenomanian affinity.

Belle Fourche Formation

Rare to common agglutinated foraminiferal species of low diversity mark the Belle Fourche Formation. In central Alberta and Saskatchewan, Cenomanian foraminiferal assemblages are poorly developed (Fig. 18, 19). The zonal marker species, *Verneuilinoides perplexus* (Loeblich) (Plate 11), is dominant and relates the Belle Fourche Formation to the *V. perplexus* Zone of Middle Cenomanian age (McNeil and Caldwell, 1981). Taxa such as *Trochammina rainwateri* Cushman and Applin, *Haplophragmoides* Cushman, *Reophax* de Montfort, *Placentammina* Thalmann, *Uvigerammina* Majzon,

Verneuilina d'Orbigny, *Saccammina* Sars, and *Hippocrepina* Parker complement the assemblage.

The dinoflagellate floras of the lower part of the Belle Fourche Formation are generally similar to those of the Fish Scales and Westgate formations. A few species are abundant in this interval, and assemblage compositions are similar. Species which last appear in the Belle Fourche Formation (Fig. 22, 23) are *Luxadinium propatulum*, *Chichaouadinium vestitum*, *Ginginodinium evittii*, *Cribroperidinium intricatum*, *Pseudoceratium expolitum*, *Dingodinium cerviculum* Cookson and Eisenack, *Gardodinium trabeculosum* (Gocht) Alberti, *Oligosphaeridium totum*, and *Odontochitina singhii*. However, in section 10-35-45-2W4, some of these species last appear in the Westgate Formation (Fig. 23). Species which range up through the Belle Fourche are *Fromea fragilis*, *Cyclonephelium vannophorum*, *Palaeoperidinium cretaceum*, and *Florentinia cooksoniae*. The upper limit of the range of *Ovoidinium verrucosum* is apparently near the base of the Belle Fourche in some sections but in others its last occurrence is in the Fish Scales Formation. *Ovoidinium scabrosum* (Cookson and Hughes) Davey also has its last

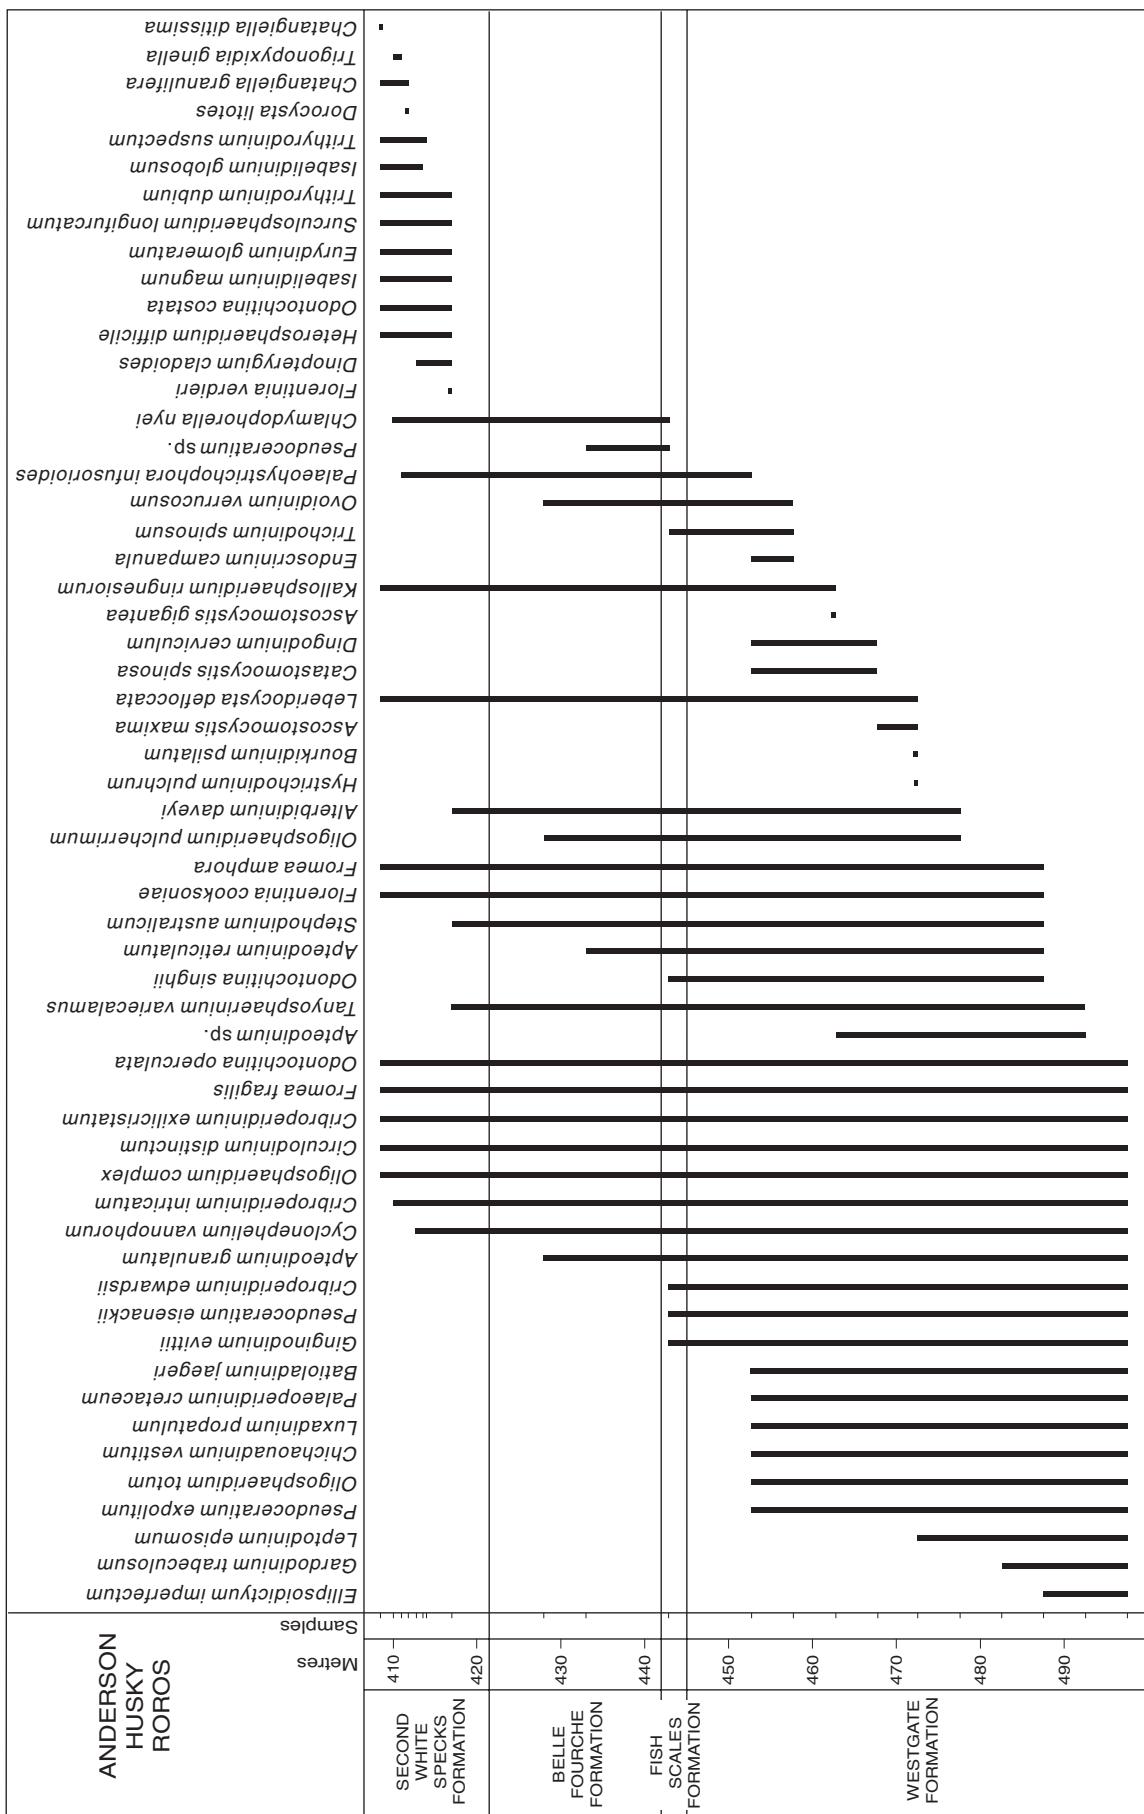

Figure 23. Dinoflagellate ranges determined from well 10-35-45-2W4, Anderson Husky Roros.

occurrence in the Belle Fourche. Other species present in the Belle Fourche, and which first appear in the upper part of the Westgate Formation, are *Ascostomocystis gigantea*, *Catastomocystis spinosa*, *Bourkidinium psilatum*, *Florentinia verdieri*, *Stephodinium australicum* Cookson and Eisenack, and *Alterbidinium daveyi* (Stover and Evitt Lentin and Williams).

The dinoflagellate assemblages are similar to those described by Singh (1983) and indicate an Early Cenomanian age for the lower part of the Belle Fourche Formation. The diversity of assemblages varies considerably between samples and some contain very few species and specimens. The upper part of the Belle Fourche Formation is marked by the first appearance of *Isabelidinium magnum* (Davey) Stover and Evitt and *Eurydinium glomeratum* (Davey) Stover and Evitt, which are commonly abundant in the interval. Upper Cretaceous species with their first occurrence in the upper Belle Fourche include *Trityrodinium suspectum* (Manum and Cookson) Davey and *Heterosphaeridium difficile* (Manum and Cookson) Ioannides. However, these species are rare. The assemblage in the upper part of the Belle Fourche indicates a Late Cenomanian age.

Second White Specks Formation

The foraminiferal fauna of the Second White Specks is characterized by the appearance of planktonic species. Compositional differences are observed between locations. At 6-34-30-8W4 (Fig. 21) the assemblage is entirely pelagic in nature, containing abundant planktonic foraminifers (over 1000 specimens/sample) of low diversity. At this location, however, faunal changes at the boundary between the Belle Fourche and Second White Specks formations cannot be recorded because of missing core. Typical species such as *Hedbergella loetterlei* Nauss, *Hedbergella amabilis* Loeblich and Tappan, *Hedbergella delrioensis* (Carsey), *Hedbergella portsdownensis* (Williams-Mitchell), *Whiteinella aprica* (Loeblich and Tappan), and *Heterohelix globulosa* (Ehrenberg) are constituents of the *Whiteinella aprica* Subzone which forms the upper part of the *H. loetterlei* Zone (Plate 12). Caldwell et al. (1978) have assigned an Early Turonian age to the *W. aprica* Subzone, whereas McNeil and Caldwell (1981) extend the age to early Middle Turonian.

At 6-18-45-1W4 (Fig. 24) the faunal assemblage of Second White Specks Formation is characterized by a two-fold subdivision. The lower interval contains a mixed

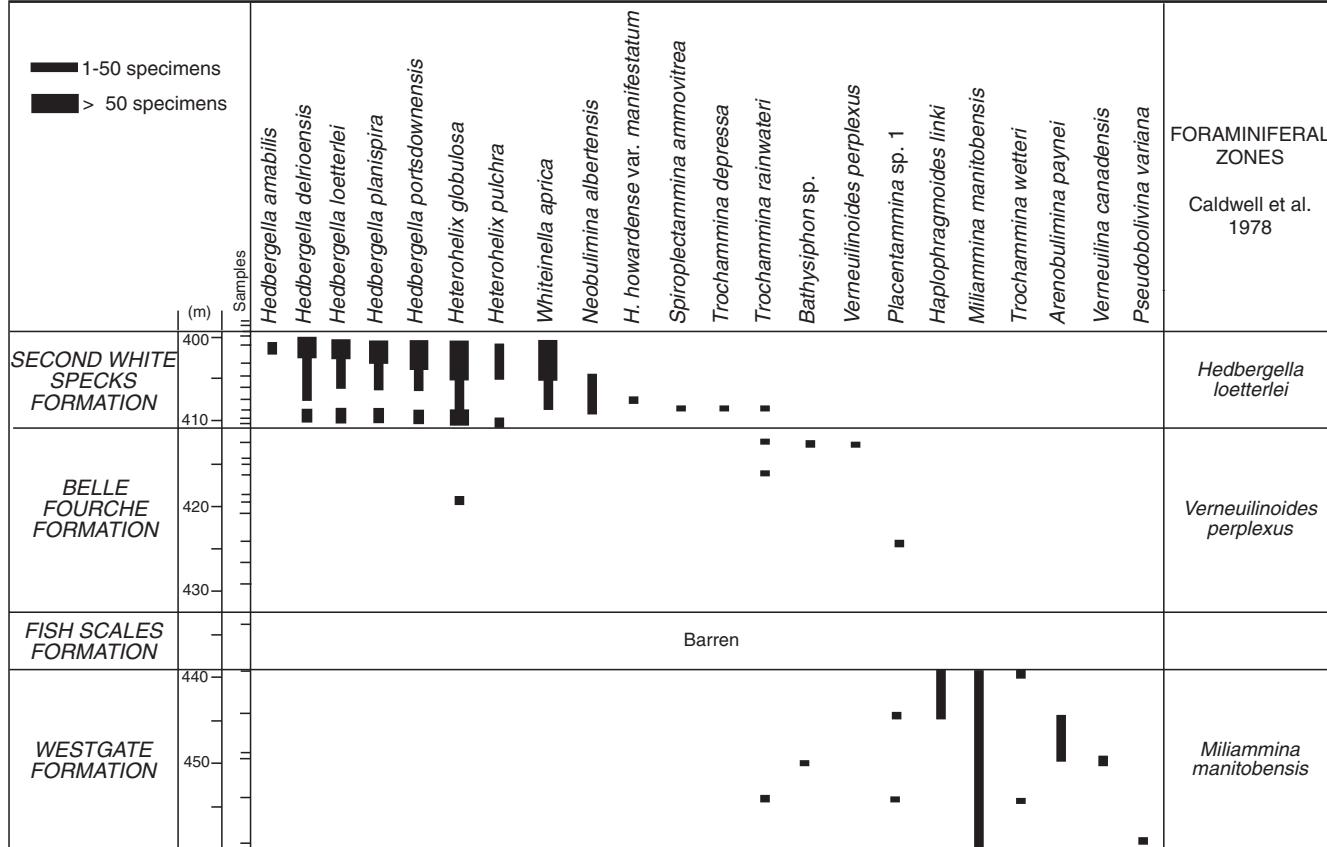

Figure 24. Biostratigraphic ranges of selected foraminiferal species at 6-18-45-1W4 in eastern Alberta. A transitional zone in the lower Second White Specks Formation is indicated by the occurrence of the calcareous species *Neobulimina albertensis* and short ranges of several agglutinated species.

assemblage of agglutinated and calcareous benthic and planktonic taxa and forms a transition to the fully pelagic *W. aprica* Subzone. Subzonal marker species such as *Clavihedbergella simplex* (Morrow) typical for Saskatchewan (North and Caldwell, 1975) and Manitoba (McNeil and Caldwell, 1981), or *Haplophragmoides spiritense* Stelck and Wall, characteristic for the Peace River District (Stelck and Wall, 1954), do not occur. However, the mixed nature of the assemblage and the occurrence of *Neobuliminina albertensis* (Stelck and Wall) suggest a time equivalent interval in southeast Alberta of Late Cenomanian/Early Turonian age. This subzone cannot be identified at 10-35-45-2W4 because of missing core. The upper pelagic assemblage belongs to the *W. aprica* Subzone.

At 6-34-30-8W4 (Fig. 18) the transition between the agglutinated fauna and the pelagic fauna is gradual, as at 6-18-45-1W4. Agglutinated specimens are poorly preserved and are assigned to *Spiroplectammina phauloides*, *Ammomarginulina*, *Ammobaculites*, *Textularia*, and other ataxophragmiids. No calcareous benthic species were found. Planktonic foraminifera are not as abundant as at the other locations (Fig. 25), but suggest the presence of the *W. aprica* Subzone. In this anomalously thick section of the Second White Specks Formation, a two-fold foraminiferal zonation connected with a more definitive time frame cannot be

identified. Therefore, the Cenomanian/Turonian boundary is drawn at the first occurrence of planktonic foraminifers and coccoliths (see below). Certain faunal characteristics may have been obscured or missed completely because of the larger sample interval at this location.

The dinoflagellate assemblages of the Second White Specks Formation have many similarities to those of the underlying Belle Fourche Formation (Fig. 22, 23), including a dominance of *Eurydinium glomeratum* and *Isabelidinium magnum*. In the Second White Specks Formation, *Trityrodinium suspectum* and *Heterosphaeridium difficile*, which are rare in the Belle Fourche, locally become abundant. Other species that continue into the Second White Specks from the Belle Fourche are *Cyconeophelium vannophorum*, *Fromea fragilis*, *Florentinia cooksoniae*, *Palaeohystrichophora infusoroides* Deflandre, and *Catastomocystis spinosa*.

Some important Upper Cretaceous species make their first appearances in the Second White Specks Formation. These include *Chatangiella granulifera* (Manum) Lentin and Williams, *Chatangiella ditissima* (McIntyre) Lentin and Williams, *Isabelidinium cooksoniae* (Alberti) Lentin and Williams, and *Isabelidinium globosum* (Davey) Lentin and Williams. The dinoflagellate assemblages indicate a

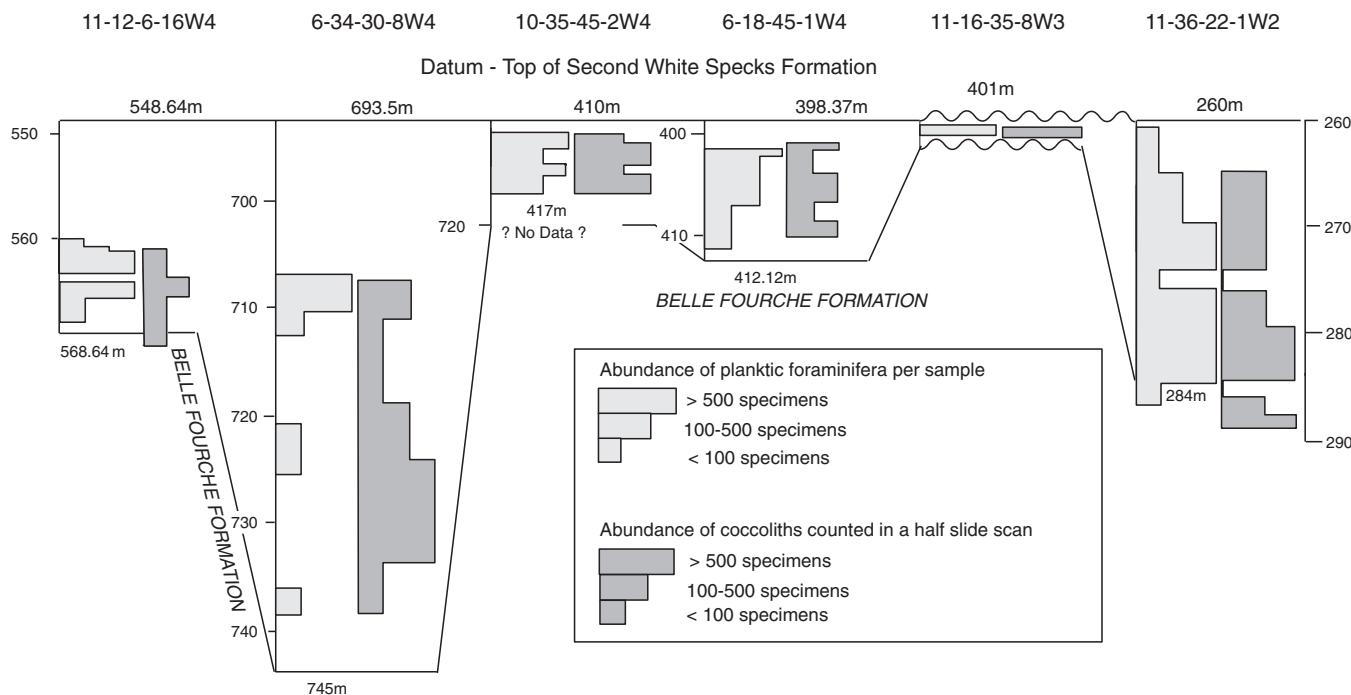

Figure 25. Relative abundance of planktic foraminifera and coccoliths in the Second White Specks Formation in a SW/E profile. At 11-12-6-16W4 and 11-36-22-1W2 coccoliths migrated into the region before planktic foraminifers. In central Saskatchewan, at 11-16-35-8W3, the Second White Specks Formation is represented by a thin interval because of unconformities at the top and at the base. It is directly overlain by the Santonian First Speckled Shale and underlain by the Belle Fourche Formation. The *Whiteinella aprica* Subzone is present whereas the *Clavihedbergella simplex* Subzone is missing.

Turonian age for the Second White Specks Formation. Abundant amorphous organic detritus, presumably of algal origin, is also present.

Generally, nannofossils first appear in the Second White Specks Formation (Dawson, 1874). Exceptions to this have been observed in eastern Saskatchewan (11-36-22-1W2) and south-central Alberta (11-12-6-16W4; see Fig. 25). Coccoliths occur as individual clasts or more commonly as aggregates in the remains of copepod fecal pellets (McNeil, 1984; Houghton, 1991) and give the Second White Specks its characteristic feature – calcareous white "specks" that are visually striking in comparison to the adjacent noncalcareous shales. Coccolith preservation is moderate to good. The assemblage (see Plate 13 and Appendix C) is dominated by long-ranging forms such as *Arkhangelskiella cymbiformis* Vekshina, *Ahmuellerella octoradiata* (Gorka), *Biscutum constans* (Gorka), *Broinsonia bevieri* Bukry, *Cretarhabdus conicus* Bramlette and Martini, *Cretarhabdus surirellus* (Deflandre), *Cribrosphaerella ehrenbergii* (Arkhangelsky), *Eiffellithus eximus* (Stover), *Eiffellithus turriseiffeli* (Deflandre), *Predicosphaera cretacea* (Arkhangelsky), *Predicosphaera spinosa* (Bramlette and Martini), *Staurolithites crux* (Deflandre and Fert), *Stephanolithion laffittei* Noel, *Vagalapilla matalosa* (Stover), *Watznaueria barnesae* (Black), *Zygodiscus acanthus* (Reinhardt), *Zygodiscus diplogrammus* (Deflandre in Deflandre and Fert), and *Zygodiscus elegans* Gartner (Thierstein, 1976; Smith, 1981, and references therein).

The assemblage also includes *Corollithion exiguum* Stradner, *Cylindralithus coronatus* Bukry, *Kamptnerius punctatus* Stradner, *Lithastrinus grilli* Stradner, *Microrhabdulus decoratus* Deflandre, *Micula decussata* Vekshina, *Micula staurophora* (Gardet), and *Zygodiscus compactus* Bukry, which have their first appearance in the Turonian. No nannofossil zonal scheme is proposed at this time for the WCSB and therefore stratigraphic correlations must rely on foraminiferal assemblages.

Sedimentation rates

Minimum and maximum compacted sedimentation rates, based on observed thicknesses and radiometric dates (Obradovich, 1991), are shown in Table 11. These rates are generalized and do not take into account periods of either nondeposition or erosion. Reconnaissance observations suggest tectonic thickening in the Rocky Mountain Foothills and the maximum observed thicknesses are likely exaggerated. Sedimentation rates are generally low, with maximum rates ranging from 2 to 6 cm/10³ yr. The highest sedimentation rates occur in the Westgate (1–6 cm/10³ yr) and Belle Fourche (0.7–5 cm/10³ yr) formations (Table 10). The lowest rates occur in the Fish Scales (1–2 cm/10³ yr) and Second White Specks formations (1.25–2.5 cm/10³ yr).

Isopachs through four slices of the lower Colorado Group in Alberta are shown in Figure 26. The isopachs indicate how basement subsidence and Cordilleran tectonics affected sedimentation. The isopach of the Westgate-equivalent interval (top of the Viking to Base of Fish Scales) shows maximum thickness of up to 400 m in northeastern British Columbia, with thinning toward the southeast. The isopach from the base of the Fish Scales Formation to the base of the Dunvegan Formation (Fish Scales and lowest Belle Fourche formations) shows a similar southeastward thinning, with maximum thicknesses over the Peace River Arch in northeastern British Columbia and northwestern Alberta.

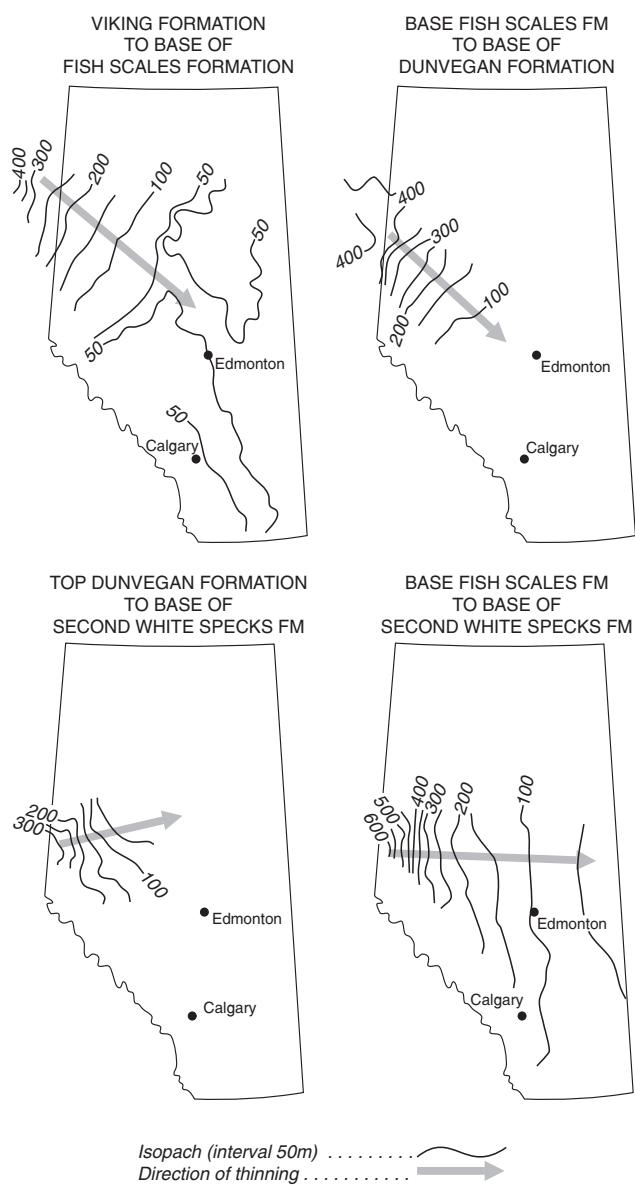

Figure 26. Isopach maps of four time slices within the Upper Albian Viking Formation to uppermost Cenomanian base of Second White Specks Formation. (Modified from Leckie et al., 1994).

Table 11**Sedimentation rates for lower Colorado Group formations (after Schröder-Adams et al., 1996)**

Formation	Age* Ma	Thickness (m)		Compacted sedimentation rate (cm/1000 yr.)
		min	max	
Westgate	99-97	20	120	6
Fish Scales	97-96	10	20	2.5
Belle Fourche	96-93	20	150	5
Second White Specks	93-91	25	50	2.75

*from Obradovich (1991)

The isopach from Dunvegan to Second White Specks Formation (most of the Belle Fourche Formation) shows a thick area on the Peace River Arch, but the thinning trend has shifted and is northeastward. The isopachs of Fish Scales and Belle Fourche formations show a general eastward thinning. Isopach maps from above the Second White Specks Formation (Leckie et al., 1994) show a general southward shift of the depocentre and basin, with thinning toward the northeast.

PALEOENVIRONMENTS

Regional paleoenvironmental conditions for the Late Albian to Middle Turonian period in the WCSB are reconstructed from the synthesis of regional lithostratigraphy, sedimentology, biofacies data, and geochronology. Paleoenvironmental changes are discussed in Schröder-Adams et al. (1996). New maps (Fig. 27) are presented to incorporate this data and also incorporate palinspastic reconstructions of McMechan and Thompson (1993). Our maps include data from maps presented for the southern portion of the Western Interior by Cobban et al. (1994) and make significant modifications to those presented by Sageman and Arthur (1994).

Westgate Formation

The major transgressive phase, which begins at the base of the Westgate Formation, follows the Viking sea-level lowstand (Leckie 1986; Beaumont 1984; Stelck and Koke 1987; Leckie and Reinson, 1993). During Late Albian time, this sea-level rise culminated in the expansion of the Mowry Sea, which extended from Colorado to the Arctic and from the Rocky Mountain Foothills to eastern Manitoba (Stelck 1975; Williams and Stelck 1975). The southern extent of this seaway is illustrated by Cobban et al. (1994, fig. 3), purportedly for the Early Cenomanian Mowry Sea (*Neogastropites americanus*). However, it is our contention that the Mowry Sea is of Late Albian age, which is consistent

with the foraminiferal data of McNeil and Caldwell (1981) and Caldwell et al. (1993). McNeil and Caldwell (1981, fig. 9) demonstrate the correlation of the Westgate Formation in the Manitoba Escarpment with the Mowry Shale in the northern United States.

The distribution of sediments deposited in the Late Albian Mowry Sea is shown in Figure 27. Essentially, most of the preserved part of the basin comprises marine shale containing fauna of Boreal affinity. The Mowry Sea (*Neogastropites americanus* time) was closed to the south in the north-central United States (Williams and Stelck, 1975; Cobban et al., 1994). The sea may have had a narrow opening or been partly restricted north of 60° (Williams and Stelck, 1975). There are no Westgate Formation sediments exposed in the Foothills of southwestern Alberta, where material was either not deposited or was eroded. In the subsurface of southern Alberta, the Westgate Formation onlaps nonmarine Mannville Group rocks. The effect of kimberlite emplacement in central Saskatchewan on Westgate sediments (Leckie et al., in press) is still poorly understood.

The abundance of benthic foraminifers, the degree of bioturbation and the presence of horizontal trace fossils such as *Planolites*, *Terebellina*, *Helminthopsis*, and *Muensteria* indicate that moderately to well-oxygenated bottom-waters were present (Ekdale et al., 1984). A diverse foraminiferal assemblage that represents numerous benthic foraminiferal feeding strategies in intervals of high bioturbation also suggests the presence of a well-oxygenated benthic environment (Koutsoukos et al., 1990; Jones and Charnock, 1985). Foraminiferal composition, including taxa of *Miliammina* Heron-Allen and Earland, *Trochammina* Parker and Jones, *Ammobaculites*, and numerous ataxophragmiids, as well as wave rippled and hummocky cross stratified, fine grained sandstone, suggest a shallow, wave-influenced sea of inner neritic to possibly middle neritic water depth. The formation is characterized by low TOC values (< 2wt%) and dominantly Type III organic matter (Fig. 4, 7); the latter indicates a terrestrial origin as the primary sediment source. Vertical variations in grain size, indicated by changes from mudstone to siltstone (coarsening- or fining-upward cycles), may be linked to fluctuations in relative sea level or changes in sediment source and/or supply. Changes in grain size, based on gamma-ray log signatures and visual core descriptions, are detected in the texture of agglutinated foraminiferal tests, which reflect the grain size of the substrate (Fig. 28). In some wells, two coarsening-upward cycles correspond to a concomitant change in grain size of agglutinated foraminiferal tests. Toward the top of the formation, a relative shallowing of the basin is indicated by a widespread coarsening-upward trend, an increase in foraminiferal species with coarse grained, robust tests and an increase in bioturbation. Evidence that waves affected the sea floor include hummocky cross-stratification, wave-

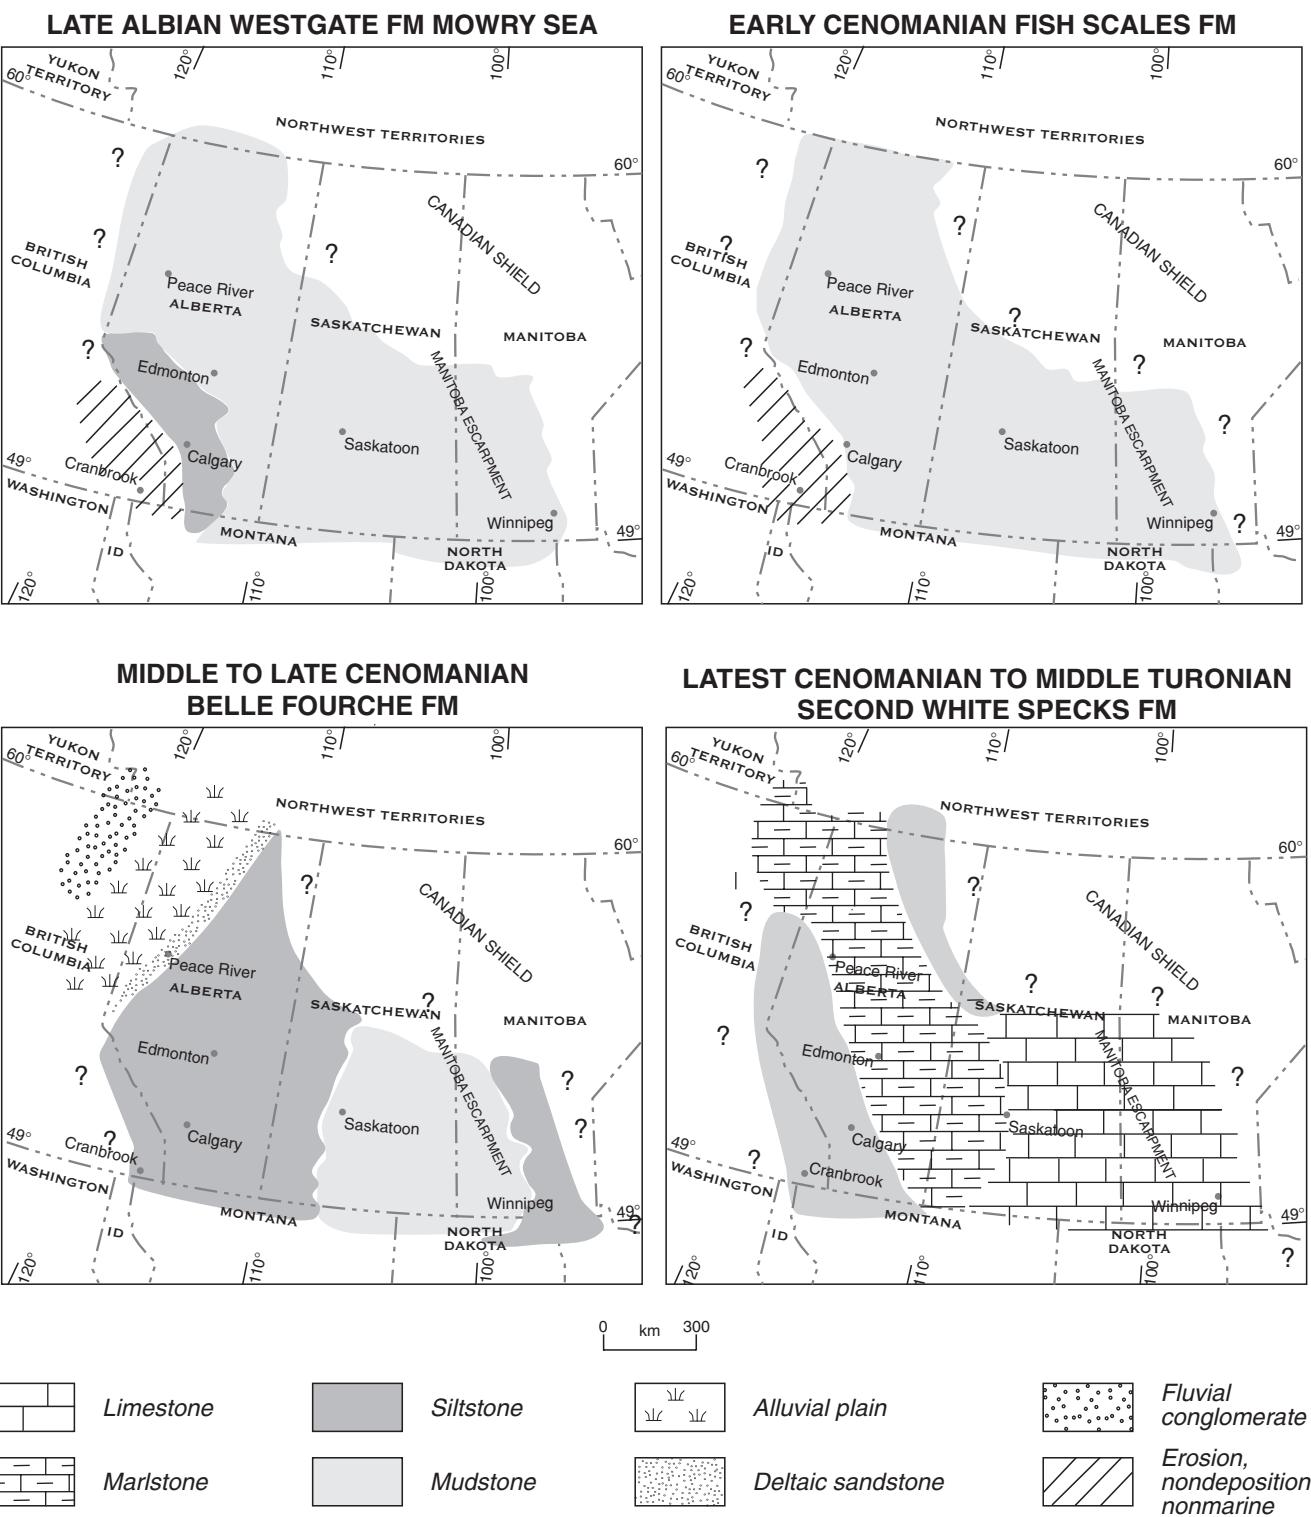

Figure 27. Paleoenvironment maps for the four formations of the lower Colorado Group.

ripples, and combined-flow ripples in thin sandstone beds. Sharp-based, graded siltstone beds in this interval may be the result of distal or low-intensity storm events.

The foraminiferal species composition shows an affinity to Arctic agglutinated assemblages of the Albian Tuktu and Grandstand formations of northern Alaska, described by Tappan (1962), Bergquist (1966), and Sliter (1979). Taxa such as *Verneuilinoides borealis* Tappan, *Textularia*

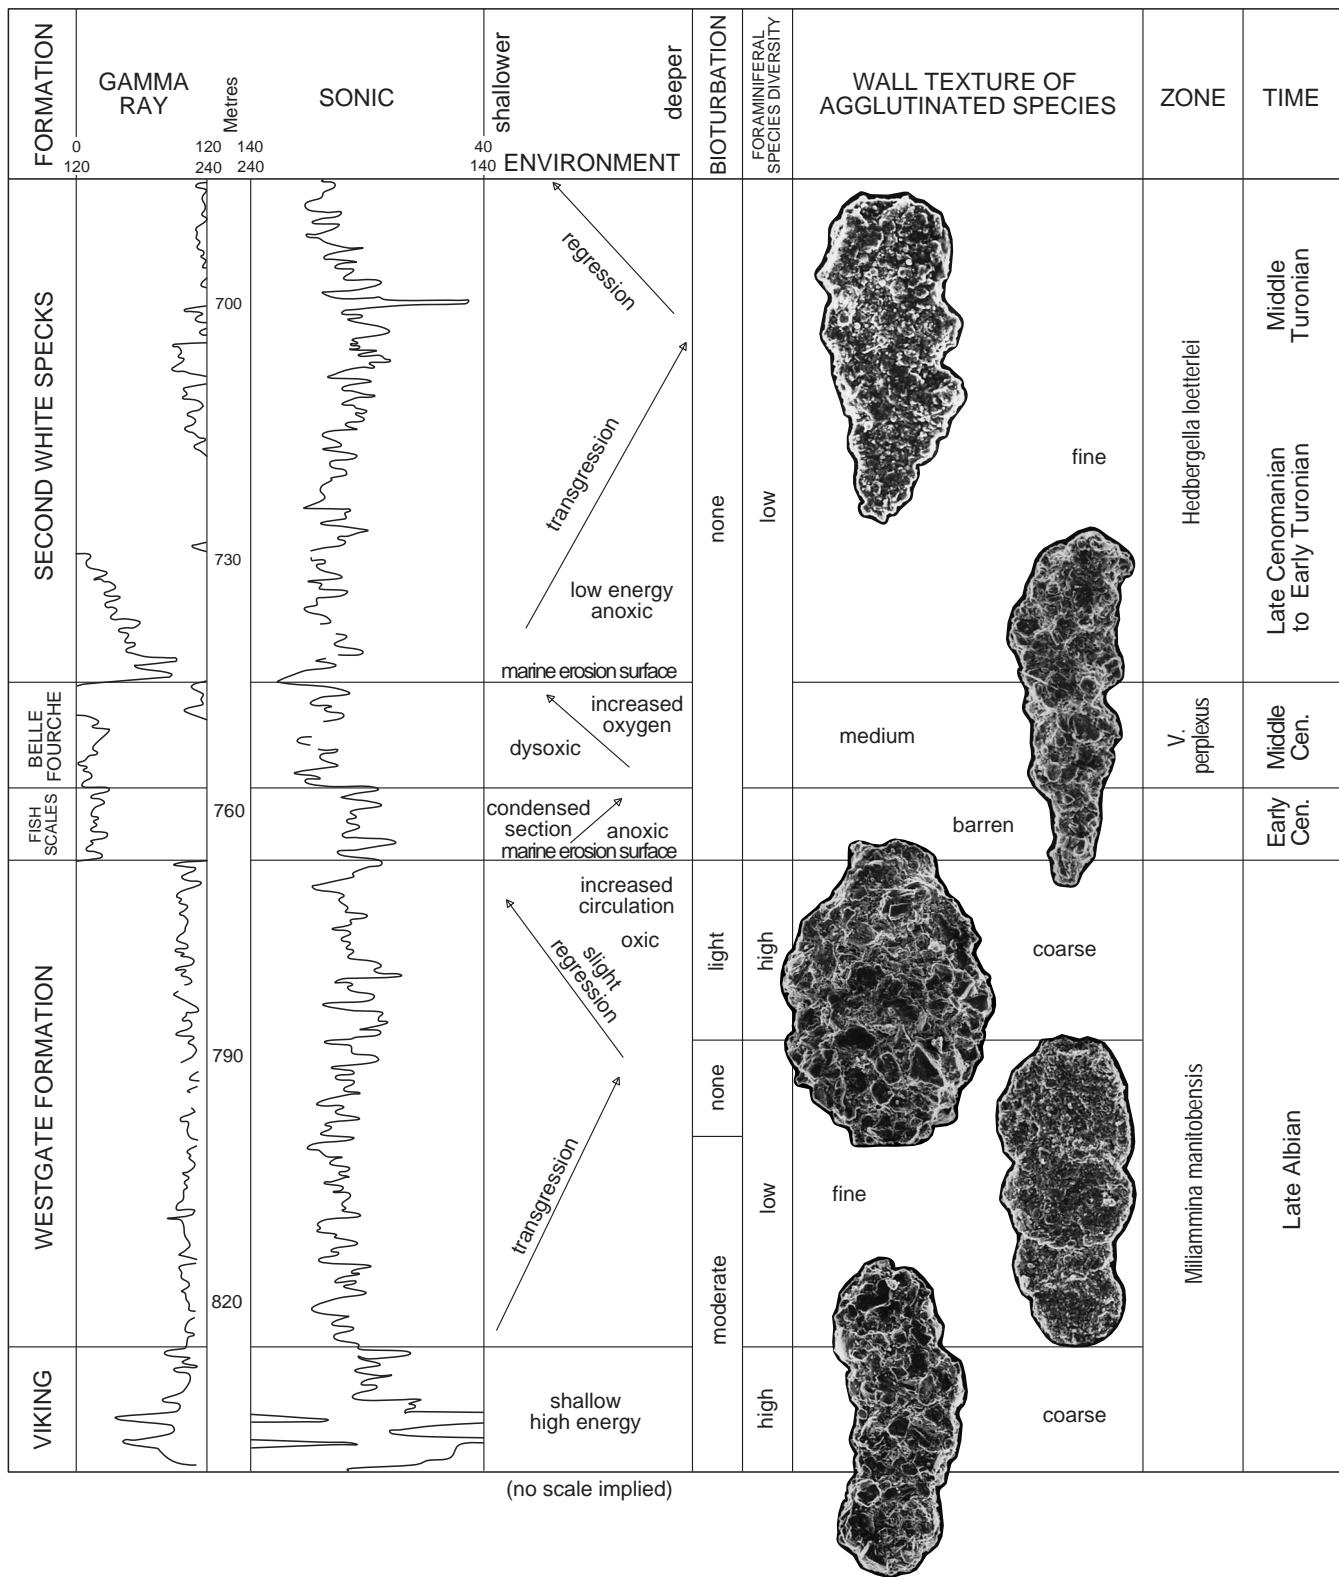

Figure 28. Summary of environmental changes in the Colorado Group at 6-34-30-8W4 in southeastern Alberta. Sandy (Viking) to silty (Westgate) substrates show increased bioturbation and contain relatively more diverse coarse grained foraminiferal assemblages, whereas fine substrates have a diminished fine grained fauna or are barren of benthic taxa. Belle Fourche and Second White Specks assemblages signal dysoxic to anoxic bottom water conditions. During the major third-order Late Albian to Turonian transgression, several smaller sea-level oscillations took place (modified after Schröder-Adams et al., in press).

topagorukensis, *Psamminopelta browsheri*, *Ammobaculites fragmentarius*, *Miliammina manitobensis*, and *Haplophragmoides topagorukensis* Tappan in both areas indicate a path of faunal exchange. Dinoflagellate assemblages also suggest the migration of plankton between the Boreal and interior Mowry seas. Among the numerous species in common are *Batioladinium jaegeri* (Alberti) Brideaux, *Chichaouadinium vestitum*, *Ellipsoidictyum imperfectum*, *Florentinia cooksoniae*, *Gardodinium trabeculosum*, *Luxadinium propatulum*, *Odontochitina singhii*, *Oligosphaeridium totum*, *Ovoidinium verrucosum*, *Palaeoperidinium cretaceum*, and *Pseudoceratium expolitum* (Doerenkamp et al., 1976; Brideaux and McIntyre, 1975; Dixon et al., 1989; May, 1979; May and Stein, 1979).

The exclusively agglutinated foraminiferal assemblage over such a wide, shallow basin is unique and lacks modern analogs. During the latest Albian, the Mowry Sea had no connection with the Tethys to the south and therefore probably had a cool, low-salinity water mass of Boreal affinity (Stelck, 1975). Brackish water conditions, inferred from oxygen isotope data from Westgate Formation concretions (Fig. 17), may have limited foraminiferal populations.

Fish Scales Formation

In Canada, at the Albian–Cenomanian boundary, drastic environmental changes occurred that resulted in the loss of benthic foraminiferal assemblages (Fig. 18, 19), increased organic-matter content (Fig. 7), a change in organic matter type (Fig. 4), and widespread bottom-water anoxia. Cobban et al. (1994) considered that the Mowry Sea was Early Cenomanian, based on ammonite occurrences. This, however, is not consistent with our foraminiferal and dinoflagellate zonations.

During the Early Cenomanian transgression associated with the Fish Scales Formation, most of the basin was inundated by marine waters, except in southwestern Alberta, where the sediments were either not deposited or were eroded (Fig. 27). Coarse grained clastic sediment of the Barons and Fish Scales sandstones along the Rocky Mountain Foothills and adjacent subsurface indicate a Middle Cenomanian drop in relative sea level and subsequent reworking during the Late Cenomanian to Turonian transgression.

The boundary between the Westgate and Fish Scales formations is a sharp lithological contact, typically expressed as a thin, parallel- or crosslaminated sandstone or pebble layer with abundant disarticulated fish and other vertebrate remains overlying shale. Leckie et al. (1992) suggested three possible mechanisms to explain deposition

of the coarse grained basal sediment within the Fish Scales Formation at the Judah outcrop in northern Alberta. The first is that a sharp drop in sea level at the end of the Albian resulted in submarine erosion and the formation of a lag deposit. In the Peace River area, Stelck et al. (1958) described the *Textularia alcesensis* Zone from the uppermost Albian to Lower Cenomanian. The absence of this zone over the broad area of the WCSB (Caldwell et al., 1978; Caldwell and North, 1984; Bloch et al., 1993) may be explained by a disconformity, suggesting that the basal deposit of the Fish Scales Formation is a lag. This faunal assemblage is reported only in northwestern Alberta and northeast British Columbia, and the limited distribution of the *T. alcesensis* Zone may also reflect localized facies development.

The second proposed mechanism is that the Fish Scales Formation was deposited during continued transgression. Minor changes in the dinoflagellate assemblage at this boundary (Fig. 22) indicate no significant change in surface waters. Sea-level rise resulted in the deposition of a condensed interval comprising concentrated fish debris (Leckie et al., 1992; Leckie and Smith, 1992). The Fish Scales Formation exhibits numerous features of a condensed section, as described by Loutit et al. (1988). It is relatively thin; contains considerable bioclastic debris indicating low sedimentation rates; has a high Type II organic matter content, and contains numerous bentonite layers.

A third mechanism, which is also based on continued sea-level rise, suggests that the bioclastic debris was winnowed from the substrate by vigorous bottom currents (Leckie et al., 1992). These currents may have been generated when two separate water masses (Tethyan and Boreal) joined to form the Western Interior Seaway (WIS), sometime in the Early Cenomanian (Hay, 1989; Hay et al., 1993). The submarine erosion caused by these currents may also have removed sediments of the *T. alcesensis* Zone. The presence of warm Tethyan waters in the northern region of the seaway, however, is problematic because Tethyan nannofossils and planktic foraminifera, such as *Hedbergella* Brönnimann and Brown, and *Heterohelix* Ehrenberg, are not found. Both genera are known to be the hardest planktic foraminifers to make their first appearance in the WIS during the Greenhorn transgression (Leckie et al., 1991) and rare occurrences of these taxa are reported from Lower Cenomanian sections only as far north as Colorado (Eicher and Diner, 1985; Caldwell et al., 1993).

Regardless of the causal mechanism(s), the sharp basal lithological contact, the occurrence of bioclastic conglomerate and the abrupt disappearance of agglutinated species suggest a period of marine erosion at the Albian–Cenomanian boundary. This boundary in the WCSB coincides with an unconformity in Arctic Canada that is associated with sea floor spreading in the Amerasia Basin

(Embry and Dixon, 1990; Dixon, 1993). It also approximately coincides with, or just postdates, an episode of kimberlite emplacement in central Saskatchewan (Gent, 1992). A possible link between these events invites further investigation.

Belle Fourche Formation

The contact between the Fish Scales and Belle Fourche formations is conformable. A slight and gradual improvement of conditions for benthic organisms during Belle Fourche deposition is indicated by a return of agglutinated foraminifers (Fig. 18, 19). Low abundance and low species diversity might have resulted from stressed benthic conditions. Cold and low-salinity waters of Boreal origin continued to dominate the WIS (Cadrin, 1992; Eicher and Diner, 1985; Caldwell et al., 1993). A remnant connection to the south (Tethys) and the wide extension of the Boreal water mass are implied by distributions of the same agglutinated taxa over the entire WIS (e.g., Eicher, 1967; Eicher and Worstell, 1970; Loeblich, 1946). South of the Canada/U.S. border, marine conditions continued to support rare occurrences of planktic foraminifera in the partially time-equivalent Graneros Shale in Colorado (Eicher and Diner, 1985, 1989), South Dakota and Wyoming (Eicher and Worstell, 1970). In Canada, the prevalence of Boreal waters prevented planktic foraminifers and coccoliths from colonizing northern regions during most of the time of Belle Fourche deposition.

In northeast British Columbia a major clastic wedge prograded southeastward, depositing the deltaic sediments of the Dunvegan Formation (Stott, 1982; Bhattacharya and Walker, 1991). Much of the finely interbedded sandstone, siltstone and shale of the Belle Fourche Formation is related to Dunvegan sedimentation. The abundance of finely interbedded sandstones and siltstones in southwest Alberta indicates a probable deltaic source to the west. Palinspastic reconstructions (McMechan and Thompson, 1993) reposition Belle Fourche sediments, now in the Rocky Mountain Foothills, to a position 70 to 160 km to the southwest. An easterly to northeasterly sediment source, from the craton, is indicated by an increased abundance of detrital illite near the Saskatchewan-Manitoba boundary (Caritat et al., 1994a). Sediments are finer grained seaward, toward the centre of the basin. The distribution of Middle to Late Cenomanian Belle Fourche sediments is shown in Figure 27.

Bottom-oxygen levels changed from anoxic during Fish Scales deposition to dysoxic during Belle Fourche deposition, which allowed a few opportunistic agglutinated foraminiferal species to colonize the substrate. Unstable environmental conditions are reflected by abrupt fluctuations in total numbers of one or two dinoflagellate

(Leckie et al., 1992) and foraminiferal species (Appendix B). A similar pattern was observed in the Belle Fourche Member of the Ashville Formation in the Manitoba Escarpment (McNeil and Caldwell, 1981) and in Cenomanian sediments of Wyoming and Montana (Eicher, 1967). Numerical modeling of paleoceanic circulation in the WIS suggests that circulation was generally storm-dominated with currents affecting the sea floor down to 200 m (Erickson and Slingerland, 1990). Brief increases in oxygen levels at the sediment/water interface can be achieved by the breakdown of water mass stratification during storms. Storm-related oxygenation events have been invoked as the mechanism of colonization by macrofaunal communities in the Cenomanian Hartland Shale Member (Greenhorn Formation; Sageman, 1989).

In northwestern Alberta, progradation of the Dunvegan Delta is attributed to a Middle Cenomanian sea-level lowstand (Bhattacharya and Walker, 1991). A lowering of sea level may destabilize a stratified water column by reducing water depth, intensifying storm-related oxygenation or changing circulation patterns. A relatively rapid sea-level rise after the Middle Cenomanian lowstand is indicated by nannofossil and planktic foraminiferal occurrences in the uppermost Belle Fourche at 11-12-6-16W4 and at 11-36-22-1W2. These occurrences signal the first presence of Tethyan-sourced waters in the Canadian part of the WIS.

Second White Specks Formation

During the latest Cenomanian to Early Turonian, sea level in the WIS reached a maximum (Kauffman, 1977, 1984; Haq et al., 1988; Kauffman et al., 1993; Caldwell et al., 1993) and the Second White Specks Formation was deposited at this time. Warm Tethyan waters of normal salinity entered the northern parts of the basin and fostered the northern migration of planktic foraminifera and coccoliths (Fig. 18, 19, 21, 25). Dinoflagellate assemblages also became more diverse near the Cenomanian/Turonian boundary (Fig. 22, 23). Thin, rippled, nannofossil-bearing sand laminae are inferred to be the result of bottom-flowing, unidirectional currents in the seaway. Sedimentary structures do not indicate significant wave activity or influence and this is evidence for deposition in relatively deep water, primarily below storm wave-base. The abundance of pelagic organisms, coupled with widespread bottom water anoxia, resulted in high TOC values (up to 12 wt%) of dominantly Type II organic matter (Fig. 4).

The distribution of Latest Cenomanian to Early Turonian Second White Specks sediments is shown in Figure 27. The southern margins of the seaway in the United States (at *Collignoniceras woollgari* time) are shown by Cobban et al. (1994) and it is inferred that the shoreline shifted markedly to the west in west-central Montana. This is consistent with

our observations from the Rocky Mountain Foothills, which would place the Second White Specks shoreline considerably west of Cranbrook, British Columbia, when Foothills outcrops are palinspastically restored (McMechan and Thompson, 1993). The shoreline trend for western Canada illustrated by Sageman and Arthur (1994) should be placed at least 200 km west of their indicated position. East of the Alberta–Saskatchewan boundary and across Saskatchewan, shales of the Second White Specks Formation grade from marlstone to limestone.

A northward decrease in surface-water temperature is indicated by the progressively smaller number of planktic foraminiferal and coccolith species in the Second White Specks Formation in Canada compared to the Greenhorn Formation of the United States (Eicher, 1969; Eicher and Worstell, 1970; Eicher and Diner, 1985). No keeled planktic foraminifers, with the exception of one questionable specimen of *Praeglobotruncana delrioensis* Loeblich and Tappan in the most southern well at 10-25-1-27W3, are found in the WCSB. The most northern reported occurrence of Late Cenomanian keeled foraminifers are from the Cone Member of the Marias River Formation in northern Montana and southernmost Alberta (Lang and McGugan, 1988). Keeled genera are the deepest-dwelling mid-Cretaceous planktic foraminifers and are regarded as being the most sensitive to environmental change (Leckie, 1987).

Persistent bottom-water anoxia is indicated by a lack of benthic foraminifers at most localities (Appendix B) and the widespread occurrence of well laminated, non-bioturbated sediments. During the latest Cenomanian to Early Turonian sea-level highstand, warm, normal-marine waters from Tethys entered the WCSB and extended to northern Canada and Alaska. Planktic foraminifers in the Turonian Seabee Formation of the Arctic North Slope of Alaska (Tappan, 1962) indicate the northernmost extent of Tethyan waters. The lack of calcareous and agglutinated benthic foraminifers in most cores indicates persistent bottom-water anoxia in the northern part of the sea, in contrast to the south (Arthur et al., 1985; Eicher and Diner, 1985). A Lower Turonian zone, rich in benthic species, was described from the Great Plains (Eicher and Worstell, 1970) and from the Black Mesa Basin in Arizona (Leckie et al., 1991), but was not found in the WCSB. It was implied that increased benthic species diversity was the result of more vigorous circulation between the WIS and the Tethys during peak transgression. However, by the time these waters reached the northern regions, they were oxygen depleted and did not support a diverse benthos. Hay et al. (1993) suggested that the mixing of southern and northern water masses during the Cenomanian produced a dense, oxygen-poor intermediate body of water. The gradual northward incursion of these oxygen-depleted waters into Canada may have resulted in widespread anoxic benthic waters. Outflow either to the north or to the south was balanced by the inflow of northern and southern surface

waters, which created major plankton kills during mixing. This introduced large amounts of organic matter into the lower water column, creating an extensive oxygen minimum zone (Hay et al., 1993). The characteristics of the Second White Specks Formation are consistent with this hypothesis. Faunal evidence for an oxygen minimum zone was also found in the Black Mesa Basin and linked to the incursion of warm waters from the south (Leckie et al., 1991).

In contrast to the lack of benthic foraminifers, bivalves, primarily of the genus *Inoceramus* Sowerby, are especially abundant throughout the Second White Specks Formation. Inoceramids were epifaunal suspension feeders that rested above the sediment–water interface, and did not burrow (Hattin, 1982). These organisms evidently survived environmental conditions, including anoxia, that were limiting factors for others (Kauffman, 1988; Sageman, 1989). The number of fragmented calcite prisms in the sand-sized fraction increases significantly at the top of the formation where planktic foraminifers and coccoliths disappear. This suggests that inoceramids continued to thrive during the initial stages of the Turonian regression.

Above the Second White Specks Formation, a basinwide sea-level drop is recorded by the change in organic-matter type (to Type III), the disappearance of planktic foraminifers and coccoliths, and the introduction of coarser grained clastics, culminating in the deposition of *Cardium* sandstones and conglomerates (Fig. 1).

In central Saskatchewan two unconformities (Fig. 29) are prominent in some cores (e.g., 11-16-35-8W3). A thin interval of the Second White Specks Formation, identified in only one sample, is preserved (Appendix B). This sample contains foraminifers of the *Whiteinella aprica* Subzone of Early Turonian age and overlies directly the *Verneuilinoides perplexus* Zone of Middle to early Late Cenomanian age. The *Clavihedbergella simplex* Subzone of latest Cenomanian to earliest Turonian age (McNeil and Caldwell, 1981) is missing. Also absent is a transitional zone that includes the benthic calcareous taxon *Neobulimina albertensis*, which is present in the section at 6-18-45-1W4. These missing subzones are interpreted as indicating a local unconformity spanning the Cenomanian–Turonian boundary.

The second unconformity is indicated by the occurrence of Santonian sediments of the First White Speckled Shale (Fig. 1, 29) directly overlying the Second White Specks Formation. The Santonian age is determined by the occurrence of the *Globigerinelloides* sp. Zone (Caldwell et al., 1978) and the nannofossil assemblage with common occurrences of *Kamptnerius magnificus* Deflandre and *Marthasterites furcatus* (Deflandre). The unconformities are mapped in a west-to-east cross-section of well logs across Saskatchewan (Fig. 29). To the south at 10-25-1-27W3,

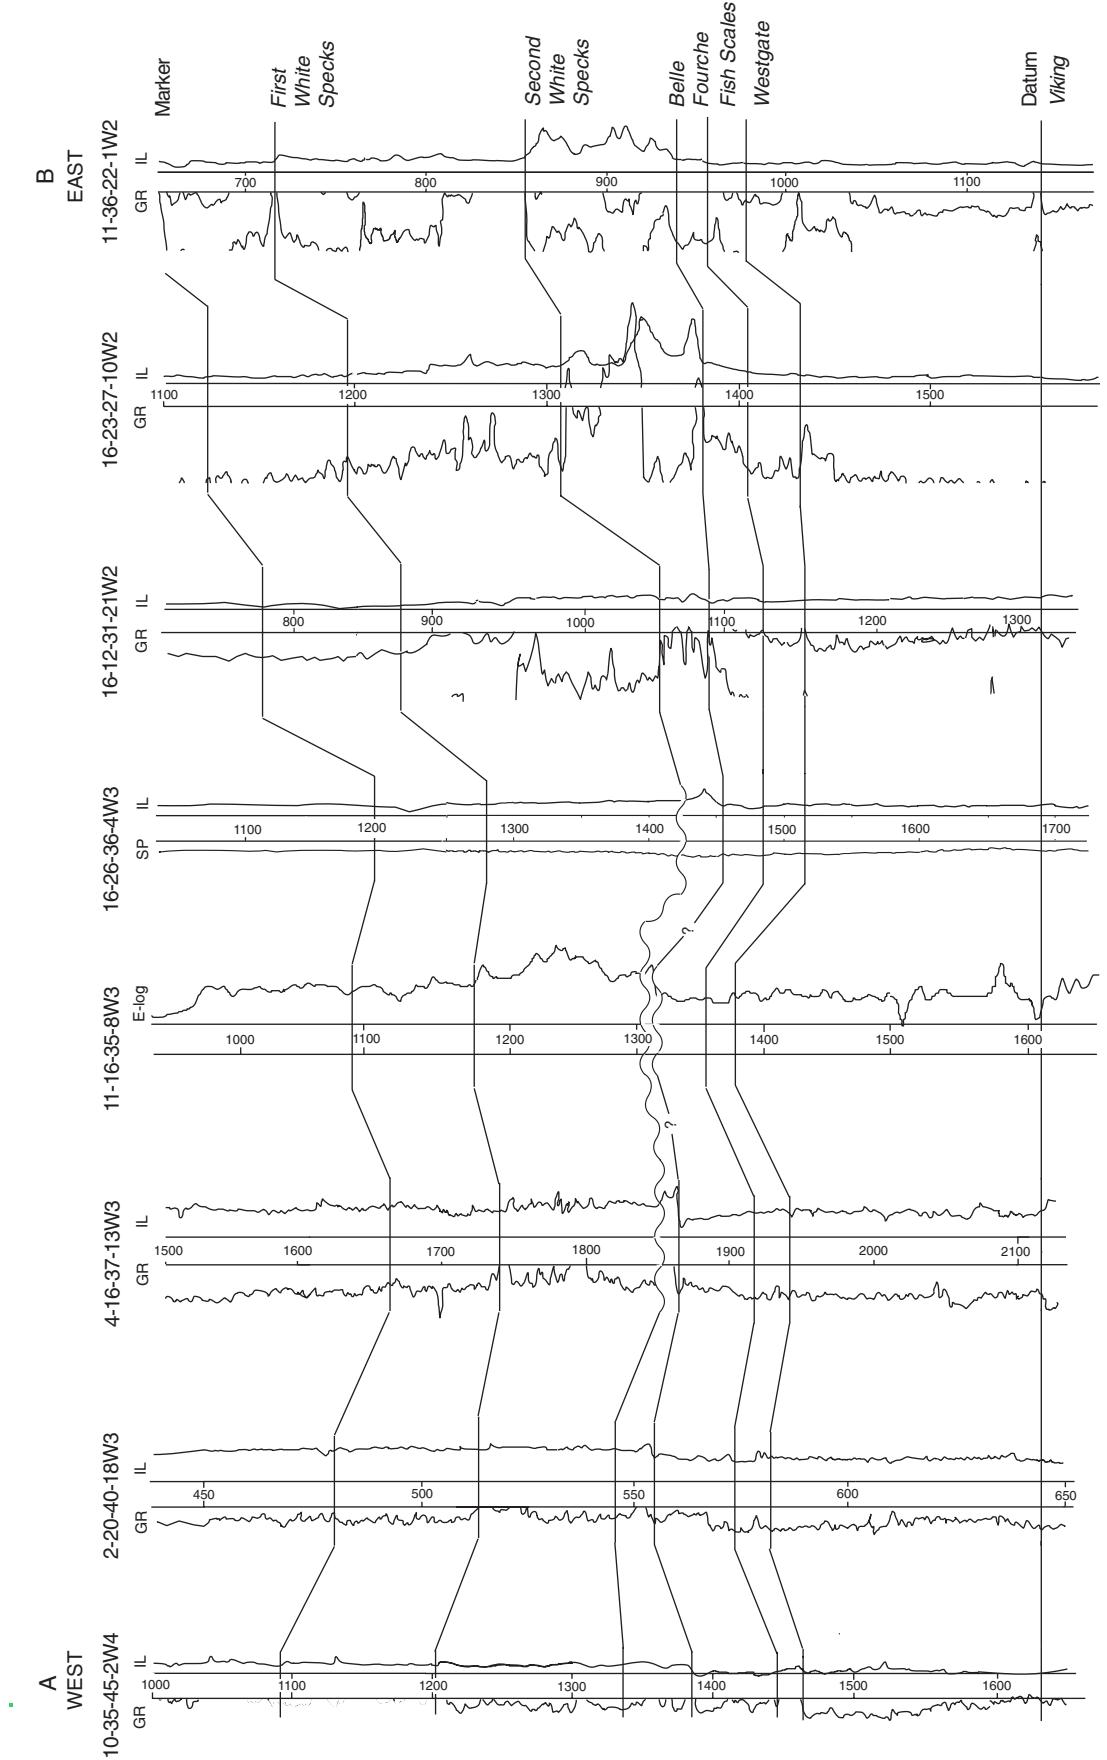

Figure 29. East–west cross-section across Saskatchewan (see Fig. 2 for location) using the Viking Formation as datum (after Schröder-Adams et al., in press). Note thinning due to erosional unconformities in 11-16-35-8W3.

Santonian nannofossil assemblages occur in an interval just above the Second White Specks Formation, indicating that the second unconformity may extend to the southwest. At this locality, it cannot be determined if Santonian sediments directly overlie Lower Turonian sediments because of a barren zone (Morden Formation?) of 3 m between the Second White Specks Formation and the First Speckled Shale (Appendices B, C).

The regional cross-section through the Colorado Group in Saskatchewan (Fig. 29) demonstrates the relatively flat, conformable stratigraphy of the lower Colorado Group except for the area in east-central Saskatchewan (11-16-13-8W3) where marked unconformities occur over an apparent structural high.

Bioclastic conglomerate

The Fish Scales and Second White Specks formations contain horizons of bioclastic conglomerate, a few centimetres to a few decimetres thick, which occur discontinuously across the basin (e.g., Leckie et al., 1992; Bloch et al., 1993). Bioclastic conglomerate associated with the Second White Specks Formation consists of fish and shark teeth, fish scales, disarticulated vertebrate remains, angular to subangular clasts of mudstone and a green, chloritic, marine clay. Rare extraformational pebbles (commonly chert or quartz clasts) up to 2 cm in diameter and coalified wood debris may be present locally. Bed thicknesses vary from 2 to 20 cm. The conglomerates are generally massive, although crude subhorizontal bedding occurs locally. On exposed surfaces of the conglomerate, tapered shell or bone bioclasts are aligned, indicating current activity. Alignment in overlying laminae may be in the opposite direction, suggesting the influence of wave action.

A bioclastic conglomerate or coarse grained sandstone, a few centimetres to decimetres thick, commonly occurs at the base of the Fish Scales Formation, in sharp contact with the underlying Westgate Formation (see Leckie et al., 1992; Bloch et al., 1993). This conglomerate is more regionally persistent than that at the base of the Second White Specks Formation. Both conglomerates are largely bioclastic, although with a different composition. The Fish Scales conglomerate may locally contain a larger siliciclastic component comprising chert or quartz, intraformational shale clasts and siderite clasts. Other components include belemnites and phosphatized bioclastic debris.

A horizon of bioclastic conglomerate has been used as a marker for the base of the Second White Specks Formation (Bloch et al., 1993). However, at 11-12-6-16W4 and 6-34-30-8W4, bioclastic conglomerate is overlain by beds containing an agglutinated Belle Fourche microfauna. In central Saskatchewan at 11-16-35-8W3, a bioclastic

conglomerate is associated with an unconformity spanning the Cenomanian–Turonian boundary. In contrast, at 6-18-45-1W4 and 11-36-22-1W2, where there is no conglomerate between the Belle Fourche and Second White Specks formations, the microfauna shows a transitional zone that contains the calcareous benthic taxon *Neobulimina albertainensis* (6-18-45-1W4) or the *Clavihedbergella simplex* Subzone (11-36-22-1W2) (Fig. 19). In southern Saskatchewan at 10-25-1-27W3, a bioclastic layer occurs at the top of the Second White Specks Formation. At this locality, the bioclastic layer is probably linked to a later unconformity that places the First White Speckled Shale (Santonian) on Turonian Second White Specks Formation. Other occurrences of coarse bioclastic layers in marine shales of the Western Interior Sea are reported from the Central Great Plains and southern Rocky Mountains of the U.S. Extensive skeletal grainstones are described from the basal Lincoln Limestone of Late Cenomanian age (Hattin, 1986).

The origin of these Late Cenomanian conglomerate layers associated with the organic-rich, deeper water marine shales is enigmatic. Locally, missing faunal zones indicate a marine erosion surface; there is no evidence from the WCSB to suggest subaerial exposure. The sporadic distribution of a conglomerate at the base of the Second White Specks Formation most likely reflects varying water depths in the basin. Where the basin was shallower, such as in central Saskatchewan, a drop in base level resulted in winnowing and erosion of older sediments. The occurrence of species of the *V. perplexus* Zone above the bioclastic layers at 11-12-6-16W4 and 6-34-30-8W4 indicates this erosional event occurs at a similar stratigraphic position to that of the erosional event within the Dunvegan Formation (Bhattacharya and Walker, 1991). In the Pasquia Hills of east-central Saskatchewan, vertebrate faunal assemblages from a time-equivalent bioclastic conglomerate suggest reworking of sediment that was initially deposited in a nearshore to possibly estuarine depositional setting (Cumbaa et al., 1992; Cumbaa, 1993). The disarticulated bioclastic layers are interpreted as being evidence of basin shallowing and subsequent winnowing on the sea floor. Alternatively, the conglomerates may be winnowed lags, which result from storms that are able to reach the sea floor at a lower base level. Beds of aligned, tapered bioclasts aligned oppositely in succeeding laminae are evidence for wave reworking. However, wave activity would be expected to form coarse grained ripples (cf., Leckie, 1986) which we have not observed.

DIAGENESIS

The early diagenesis of marine shales is commonly dominated by microbial processes that oxidize organic matter and may result in mineral dissolution or authigenesis

(Gautier and Claypool, 1984; Gautier et al., 1985; Gautier, 1986; Pratt et al., 1992). The hierarchy of microbial redox processes reflects the decreasing availability of oxygen in organic-matter-bearing sediments during burial and the free-energy yields of the specific reactions (Berner, 1980). This reaction hierarchy is commonly described as a series of diagenetic zones characterized by the dominant redox reaction. With increasing depth, these zones include aerobic oxidation, nitrate reduction, manganese and iron reduction, sulfate reduction and methanogenesis (Claypool and Kaplan, 1974). However, studies of modern marine sediments indicate that these processes, particularly methanogenesis and sulphate reduction, may not be mutually exclusive (Oremland and Taylor, 1978).

Petrographic, chemical, mineralogical, and isotopic data indicate that the early diagenesis of lower Colorado Group shales is dominated by two of these reactions: sulfate reduction and methanogenesis. In addition, petrographic, isotopic, and chemical data from clay minerals indicate that clay authigenesis is also an early diagenetic process.

Late diagenesis, that is, mineral reactions that occur in response to a burial induced increase in temperature and pressure, is commonly characterized by dissolution-precipitation reactions involving silicates and carbonates, as well as organic matter maturation. Information regarding the nature of late diagenetic alteration of Colorado Group shales comes from petrographic observations, isotopic data, and XRD characteristics of clay minerals. These data indicate that late diagenesis of Colorado Group shales is dominated by quartz and feldspar dissolution, and Fe-carbonate precipitation. Caritat et al. (1994a) indicate that mixed-layer clay and/or illite authigenesis also occurs within the Belle Fourche Formation.

Sulphate reduction

As previously described, authigenic pyrite is a common constituent in the lower Colorado Group, ranging in abundance from < 0.2 to approximately 8.5 wt % (Plate 5, Table 9). This is the primary evidence for the occurrence of early diagenetic sulphate reduction. Sulphur isotopic data from pyrite also indicate that sulphate reduction is the primary reaction leading to pyrite authigenesis (Table 8).

Organic matter type and abundance, and benthic activity, are primary controls on the extent and rate of sulphate reduction within sediments (Berner, 1970; Goldhaber and Kaplan, 1974). The variability of the type and abundance of organic matter within the discrete shale units (Fig. 4) suggests that the rate and extent of reaction also will be variable from unit to unit. The shales of this interval can be divided into two groups based on their carbon-sulphur (C-S) and sulphur-iron (S-Fe) systematics (Fig. 7, 8). As

previously discussed, Group 1 is characterized by TOC and S values of < 2 wt% and Fe/S values much greater than 1. Group 2 is characterized by high TOC and S values, generally > 2 wt%, and Fe/S values greater than or equal to 1. Group 1 includes the Joli Fou, Westgate, and Belle Fourche formations and the shales of the Viking and Lea Park formations. Group 2 includes the Fish Scales, Second White Specks, and Morden formations as well as the First Speckled Shale.

Group 2 shales were deposited beneath a relatively deep, productive water column during transgressive periods, where bottom water conditions were anoxic to dysoxic. The characteristics of Group 1 shales indicate a less productive, shallower water column, with more oxygenated bottom waters and an increased sediment input. These two depositional conditions are reflected in the isotopic composition of pyrite sulphur (Fig. 30). The $\delta^{34}\text{S}$ values of most Group 2 shale samples are consistently depleted with most values < -22‰ CDT. Group 1 values are variable with a range of more than 80‰ (Fig. 30).

Using the simplest approximation of the process of sulphate reduction, the rate at which this process occurs is dependent on the reactivity of organic matter and the availability of sulphate. Under conditions characteristic of condensed sections (low sedimentation rates and high, reactive TOC content), rapid and efficient sulphate reduction results in very large and consistent depletions in ^{34}S in pyrite sulphur, as observed in the Group 2 shales. In progradational shales, where sedimentation rates are higher, and the organic matter is less reactive (contains a higher proportion of Type III OM), sulphate reduction proceeds more slowly. The rate of reduction at or near the sediment-water interface initially is controlled by the reactivity of the organic matter. With increasing burial, however, sulphate availability may become the limiting factor.

A Rayleigh distillation model (Hoefs, 1987) predicts that in a closed system (i.e., buried sediment) where the sulphate reservoir is completely consumed, the initial (sulphate) and final (sulphide) isotopic compositions approach equality. Because of the increasingly extreme ^{34}S enrichment in the residual sulphate reservoir, the instantaneous ^{34}S values of the dissolved HS^- may also show extreme enrichment. The range of sulphide ^{34}S values under conditions that may approach a "closed system", therefore, may be extremely variable, as seen in Group 1 shales (Fig. 30).

Concretion morphologies, attributes, and isotopic composition

Siderite and calcite concretions occur in Colorado Group and stratigraphically equivalent sediments in a variety of morphologies. Carbonate concretions in marine sediments

commonly result from early diagenetic processes (Irwin et al., 1977; Gautier and Claypool, 1984) and their chemistry and isotopic compositions therefore provide information about early diagenetic processes within the host sediments. The fabrics and isotopic compositions of the calcite and siderite concretions of the Colorado Group are distinct and reflect the variable influences of organic matter oxidation, including sulphate reduction, methanogenesis, and water-rock interaction.

Calcite concretions

Calcite concretions occur only within calcareous facies in the upper Belle Fourche and Second White Specks formations and may form stratigraphically continuous

horizons or stratabound lenses. Another common morphology is discrete spheroidal or elliptical concretions up to several tens of centimetres (long axis) in size. The calcite habit ranges from micrite to cone-in-cone spar. Septaria are common and may contain multiple generations of anhedral to euhedral calcite spar. Calcite concretions are generally laminated (Plate 14) and divergent laminae are observed adjacent to or within some calcite concretions, indicating very early growth beneath the sediment–water interface (Plate 14). Calcite concretions commonly have pyrite rinds up to 0.5 cm thick. This suggests growth prior to, or coincident with, the onset of vigorous sulphate reduction.

Carbon and oxygen isotopic data (Fig. 17) also are consistent with an early diagenetic origin. Calcite concretions from the Second White Specks and Belle Fourche formations are very depleted in ^{13}C ($< -10\text{\textperthousand}$ PDB) and relatively enriched in ^{18}O ($> +25\text{\textperthousand}$ SMOW). Depleted carbon values result from the incorporation of dissolved CO_2 derived from the oxidation of organic matter, probably by sulphate reduction, that occurs in the underlying sediment. In calcareous sediments, where the activity of dissolved Ca^{2+} in pore waters is likely to be high, the upward diffusion of dissolved CO_2 may result in calcite precipitation if the pH is buffered to near neutral or greater values. The oxygen isotope values reflect calcite precipitation from pore waters somewhat depleted in ^{18}O when compared to normal marine values ($\delta^{18}\text{O} = 0\text{\textperthousand}$ SMOW).

The oxygen isotopic composition of concretions is determined by the temperature of formation and the isotopic composition of the pore waters from which they form. Cadri (1992) determined from biogenic calcite and aragonite that bottom waters of the WCSB in the Late Cenomanian and Early Turonian were about $-7\text{\textperthousand}$ SMOW. Belle Fourche kaolinite and I/S isotopic values also are consistent with this initial pore-water value (Caritat et al., 1994a). Assuming that an oxygen isotopic value for pore water is $-7\text{\textperthousand}$ SMOW, the temperature of calcite concretion formation may be calculated using the calcite–water geothermometer of Friedman and O’Neil (1977):

$$1000 \ln \alpha_{\text{calcite}-\text{water}} = 2.78 \times 10^{-6}/T^2 - 2.89 \quad (1)$$

where T is in $^{\circ}\text{K}$, and the relationship between α and δ ,

$$\alpha_{\text{calcite}-\text{water}} = (\delta_{\text{calcite}} + 1000)/(\delta_{\text{water}} + 1000) \quad (2)$$

Using an average $\delta^{18}\text{O}_{\text{calcite}} = 27\text{\textperthousand}$ (see Table 7) and a $\delta^{18}\text{O}_{\text{water}} = -7\text{\textperthousand}$, the calculated temperature of formation for calcite concretions is $\sim 3^{\circ}\text{C}$. This low bottom-water temperature suggests that cool, Boreal waters that dominated the WCSB in the Albian (Schröder-Adams et al., 1996) persisted into the Turonian. This is consistent with a wealth of data (Kauffman, 1977; Pratt, 1984; Cadri, 1992) that

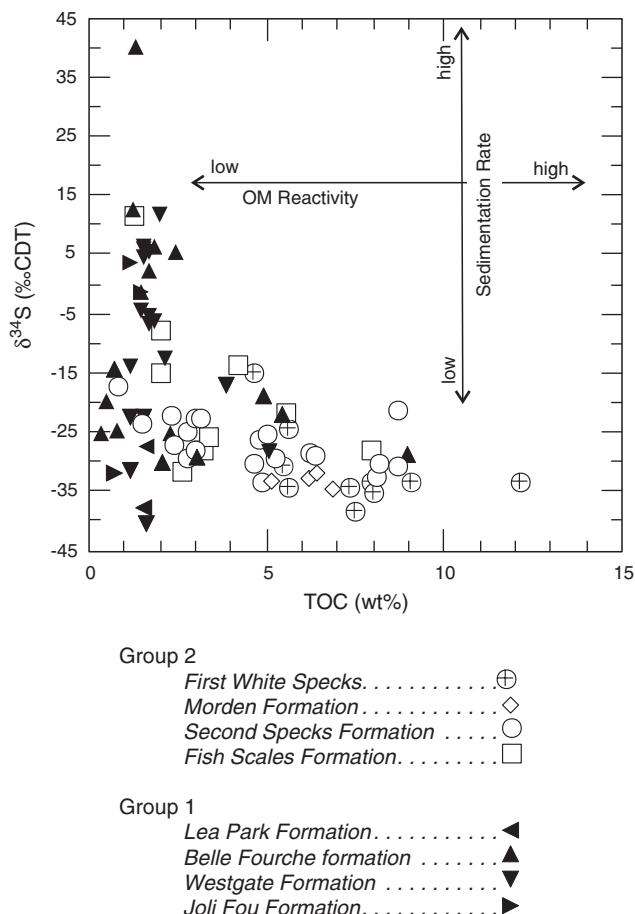

Figure 30. Total organic carbon (TOC) versus the sulphur isotopic composition (^{34}S) of pyrite from transgressive (Group 2) and progradational (Group 1) shales. Arrows illustrate the general effect of organic matter (OM) reactivity and sedimentation rate on the isotopic composition of pyrite.

indicates that the WIS was a stratified water body throughout the early Late Cretaceous.

One calcite and one dolomite sample (10-34-42-22W4-2A) show normal marine values for $\delta^{13}\text{C}$ and lower $\delta^{18}\text{O}$ values. The calcite sample is from a bioclastic-rich layer at the margin of concretion 10-34-42-22W4 (Plate 14) and the isotopic composition is interpreted as reflecting biogenic marine carbonate with some recrystallization during diagenesis, which results in the lower $\delta^{18}\text{O}$ value (22.4‰ SMOW, see below). Similarly, the dolomite sample reflects dolomitization of bioclastic carbonate during early diagenesis.

Siderite concretions

Siderite concretions occur in the Westgate, Fish Scales, and Belle Fourche formations and exhibit a range of morphologies similar to calcite concretions. In addition, large (up to 1 m in diameter) siderite kettle concretions are observed in outcrops of the Sunkay Member of the Blackstone Formation (Belle Fourche equivalent). The siderite is cryptocrystalline and concretions commonly show evidence of extensive burrowing by a variety of benthic organisms (Plates 15, 16). Disseminated siderite also occurs in well bioturbated sediments of the Westgate (Plate 6A) and Belle Fourche formations.

Siderite concretions show a range of isotopic compositions and complex textural relationships that highlight variable, but generally early, growth conditions. Siderite concretions are either isotopically zoned or unzoned.

The sediment in which isotopically zoned concretions of the Westgate Formation (Plates 15, 16) have formed shows evidence of extensive bioturbation, and individual trace fossils are well preserved, indicating relatively early siderite formation. In concretion 10-25-65-20W5-2A (Plate 16), numerous small burrows that appear as "starbursts" have circular centers and are filled with dolomite. The circular shape indicates that cementation occurred prior to any significant burial. In contrast, a large burrow preserved near the center of the concretion shows some flattening. This indicates that siderite formation occurred after loading by additional sediment.

In concretion 10-25-65-20W5-2B (Plate 15), botryoidal pyrite fills circular burrows indicating early pyritization of these structures. Burrows are commonly sites of preferential pyritization because they are organic rich and allow irrigation of the sediment by sulphate-bearing fluids (Pratt, 1984).

In the zoned concretions from the Westgate Formation, the isotopic compositions are more enriched in ^{13}C and ^{18}O in the concretion centers and $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ values decrease toward the margins (Plates 15, 16). In the unzoned siderite concretion from the Belle Fourche Formation, the $\delta^{18}\text{O}$ values are similar to those at the centres of the zoned concretions. The $\delta^{13}\text{C}$ values are positive, but not as high as the $\delta^{13}\text{C}$ values of the zoned concretions (see Table 7). The similarity of these isotopic values is interpreted as indicating that the precipitation of siderite in both zoned and unzoned concretions began under similar conditions. The growth of unzoned concretions most likely terminated early, whereas the growth of zoned concretions continued under evolving burial conditions.

The initial pore water isotopic composition for Westgate (Late Albian) concretions can be determined as above, using the siderite–water geothermometer of Carothers et al. (1988),

$$1000 \ln \alpha_{\text{siderite-water}} = 3.31 \times 10^{-6} / T^2 - 3.50 \quad (3)$$

and assuming a bottom temperature similar to that of calcite concretion formation. At 3°C, and utilizing an initial $\delta^{18}\text{O}_{\text{siderite}} = 23.5\text{‰}$ (see Table 7) the calculated $\delta^{18}\text{O}_{\text{pore water}} = -14.5\text{‰}$ SMOW. This calculation suggests that Late Albian basinal waters in the northwest part of the study area were much more depleted in ^{18}O than those of the Late Cenomanian to Early Turonian WIS in more distal portions of the basin.

Within the zoned concretions, the decrease in the $\delta^{18}\text{O}$ values of siderite to ~20.5‰ may reflect the increasing temperature of siderite precipitation during burial or a change in pore-water isotopic composition to lower $\delta^{18}\text{O}$ values. A decrease in pore-water isotopic values could result from either: 1) the incursion of meteoric waters into sediments during subsequent regression or, 2) the neoformation of clay minerals under relatively closed system conditions.

Using Equation #3, the calculated $\delta^{18}\text{O}_{\text{pore water}} = -14.5\text{‰}$ SMOW, and a concretion margin siderite $\delta^{18}\text{O}$ value of -20.5‰, the temperature of formation for the outer portions of the zoned concretions would be ~16°C. This suggests growth of the zoned concretions over ~13°C temperature increase or about 500 m of burial, assuming a 25°C/km geothermal gradient. Using the maximum sedimentation rate for the Westgate Formation (Table 10) of 6 cm/k.y., concretion growth is estimated to take up to 8 m.y.

Changes in pore water isotopic composition are difficult to constrain. The incursion of meteoric waters into basin sediments several hundred kilometres from the inferred

shoreline has been invoked as a mechanism of change in pore water isotopic composition (i.e., Machemer and Hutcheon, 1988). The zoned concretions are from the proximal northwest part of the study area, but the location of the shoreline in the Late Albian is unknown (Fig. 27). Additional study of coeval concretions to determine the geographic variability of isotopic compositions, as well as a better understanding of Albian paleogeography, is necessary to test the meteoric incursion hypothesis.

There is evidence indicating that clay mineral authigenesis occurred during early diagenesis and therefore, clay mineral authigenesis may be a viable mechanism for reducing pore water $\delta^{18}\text{O}$ values.

Early diagenetic clay mineral authigenesis

Early diagenetic authigenesis for some clay minerals is indicated primarily from petrographic data. Minor to trace amounts of a Fe- and K-rich, fibrous aluminosilicate are observed as well-rounded clots, perhaps pseudomorphs of fecal material (Plate 4a). This peloidal habit, with a Fe-rich composition, is commonly interpreted as glauconite but may also be celadonite, chlorite, nontronite, corrensite, or mixtures of these Fe-rich clay minerals. Discrete green clay minerals or mixtures of green marine clays are commonly identified petrographically as "glauconite" and the term used herein is so defined. The presence of "glauconite" in Colorado Group sediments is associated with bioturbation and/or high bioclastic input. Some textures suggest replacement of Fe-rich argillaceous clasts (Plate 4b). "Glauconite" formation has been shown to occur at or near the sediment–water interface under dysoxic conditions (Taylor and Curtis, 1995) and the textures observed in Colorado Group shales are consistent with this mode of formation, but are not unequivocal.

Early diagenetic kaolinite authigenesis (Plates 8c, 9b) is inferred from observed kaolinite habits. It has been suggested that kaolinite formation is favored under acid conditions in carbonate-poor sediments by the hydrolysis of K-aluminosilicates (Pollastro, 1981; Huggett, 1994), where:

and/or

However, Abercrombie (1988) has shown that pore water pH may be rock-buffered by hydrolysis reactions to near neutral values, even when water/rock ratios are higher than those characteristic of diagenetic conditions. Mildly acidic conditions may develop in organic-rich sediments where organic matter oxidation occurs more rapidly than buffering reactions such as hydrolysis. An alternative condition in

which kaolinite may form is when pore waters are dilute. While the specific conditions of kaolinite formation in Colorado Group shales remain unknown, petrographic observations indicate some early kaolinite neoformation.

Petrographic observations also indicate smectite and/or mixed-layer clay authigenesis occurs during early diagenesis by neoformation (Plate 3a, b) or devitrification (by hydrolysis or halmyrolysis) of volcanic ash. Caritat et al. (1994a) demonstrated a genetic relationship between the clay fraction ($< 0.2 \mu\text{m}$) composition and bentonite smectite, which suggests a tephra precursor for much of the I/S, and possibly kaolinite, in immature samples of the Belle Fourche Formation.

A compositional relationship between the shale clay fraction and bentonite is evaluated by plotting the molar compositions of each group on an element ratio diagram that widely separates both groups. This separation is achieved by plotting Si/K (y-axis) versus Al/K (x-axis) as the K content of bentonites is very low (see Table 5). A regression through the clay fraction ($< 0.2 \mu\text{m}$) compositions of two formations, the Westgate and Second White Specks (shown in Fig. 31), intersects the field of bentonite compositions, suggesting a compositional relationship. The Fish Scales Formation samples are plotted on Figure 31 but no regression is calculated because of the small number of data points.

Published clay-mineral oxygen isotope data may also be interpreted as indicating neoformation of clay minerals from a precursor volcanic ash (Caritat et al., 1994a) at low temperatures. In summary, several lines of evidence indicate that the formation of matrix clay minerals of the Colorado Group shales results, in part, from the early diagenetic alteration of volcanic ash. A similar conclusion was reached by Nadeau and Reynolds (1981) based on the composition of I/S and K/Ar data from matrix clays and bentonites of the Late Cretaceous Mancos Shale.

Clay mineral neoformation will affect the pore water $\delta^{18}\text{O}$ composition only under relatively "closed-system" conditions, where pore water exchange with the overlying basinal waters is restricted. Pore water $\delta^{18}\text{O}$ values will decrease as a result of clay mineral authigenesis because of the large fractionation factor at low temperatures (see Longstaffe, 1987). Studies of modern ocean sediments indicate a decrease of up to $\sim 4\text{\textperthousand}$ SMOW in pore water $\delta^{18}\text{O}$ values over depths of several hundred metres (Savin and Yeh, 1981). The difference in oxygen isotopic values from zoned siderite concretion suggests a decrease in pore water values of about 3\textperthousand in Westgate sediments.

Late diagenetic processes

Late, or burial-induced diagenetic effects are difficult to discern in Colorado Group shales. Some recent studies of

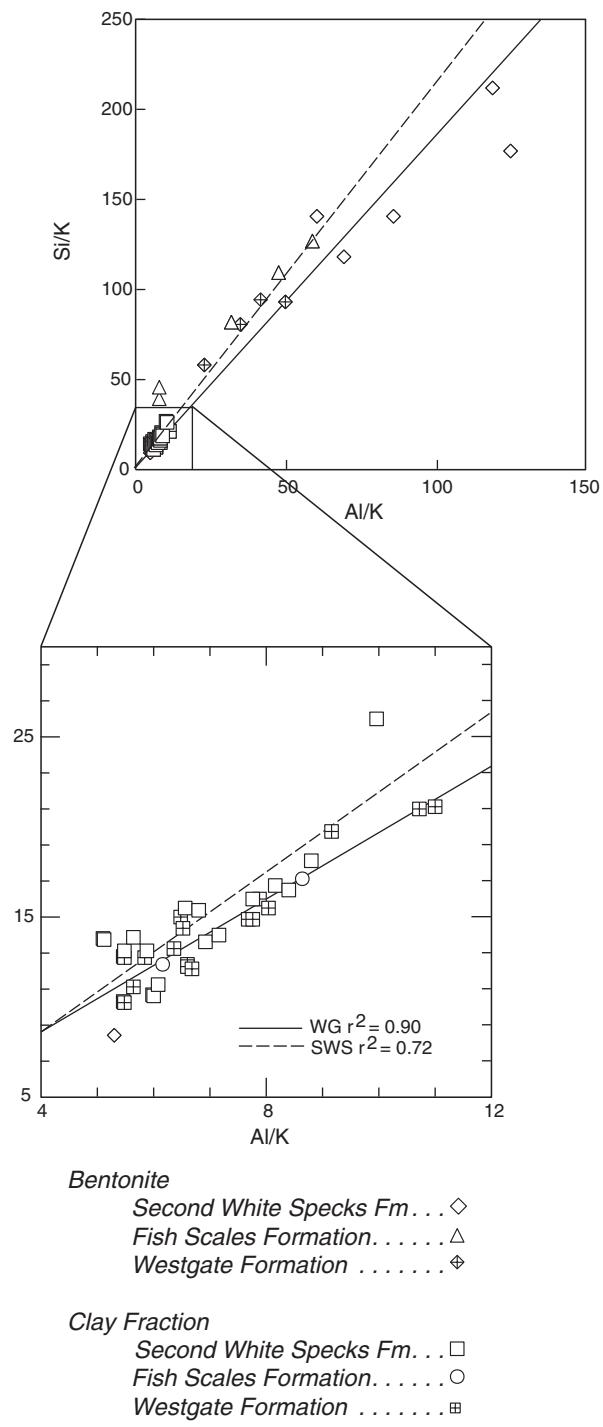

Figure 31. Al/K versus Si/K diagram for bentonites and clay fraction of shale matrix for indicated formations. Inset shows the clay fraction sample used to calculate the regression for the Westgate (WG - solid line) and Second White Specks (SWS - dashed line) formations that intersects the bentonite fields for each formation in the upper part of the diagram. No regression was calculated for the Fish Scales because of the small number of data points. See Caritat et al. (1994) for Belle Fourche Formation data.

shale diagenesis indicate that significant mineral reactions and mass transport of soluble species occur (i.e., Wintsch and Kvare, 1994, and references therein) whereas others show that little diagenetic alteration occurs in shales at depth (i.e., Bloch and Hutcheon, 1992). In Colorado Group shales, petrographic observations suggest that late diagenetic processes involve primarily the dissolution and precipitation of silicate minerals and fracture development. Significant fluid (aqueous and hydrocarbon) migration and soluble species transport may occur within fracture networks.

While early diagenetic kaolinization of silicates does occur, this process may extend well into the subsurface. Mechanical deformation of mica lathes may enhance kaolinization but not all deformed micas are pervasively altered (Plates 6b, 8d).

Well-preserved grain pseudomorphs indicate that kaolinization of feldspars (Plate 3) and perhaps volcanic clasts occurs after significant compaction and matrix stabilization.

Embayed quartz grains (Plates 1d, e, 2a) are commonly observed, suggesting that quartz dissolution is a pervasive process. Extensive dissolution that results in suturing is observed in one sample (Plates 4d-f). In this sample (#050940, 1496 m), quartz grains have extreme length to width ratios of up to 10 and are sutured in a bedding-parallel orientation. The intergranular matrix is enriched in Fe. These features are interpreted as reflecting framework dissolution by pore fluids near maximum burial depth. The rarity of these features suggests that this type of fluid movement is localized, perhaps controlled by fracture development or a localized increase in permeability due to a high silt content.

Feldspar dissolution (Plates 2d, 6a) is commonly observed in Colorado Group shales but it appears to be localized, and many K-feldspars are well preserved (Plates 1d, 7d). Plagioclase feldspar is not commonly observed and frequently shows alteration or replacement by calcite (Plate 6d).

Fe-rich carbonate is commonly observed rimming detrital (bioclastic) carbonate grains (Plate 6c). The timing of overgrowth development is difficult to discern from textural relationships but most likely follows sulphate reduction and significant concretion formation.

Fracture formation and sediment fluid isotopic compositions

Natural fractures are observed in core and outcrop, primarily in the Second White Specks Formation. Significant natural fracturing was found in only one core (Dome et al. Claresholm, Table 1). Rubble zones containing

common slickensides were noted in other cores but the origin of the slickensides and resulting rubble are unclear in many cases. Coring-induced fractures are also present (Plate 17).

Calcite-filled fractures are seen in concretionary horizons and are pervasive in some outcrops (Plates 18–21). The orientation and spacing of the fractures observed in outcrop indicate that they formed as a result of compressive (thrusting) tectonic stress and that the Second White Specks Formation behaved as a cohesive, brittle body with predictable fracture characteristics (Plates 18–20). In contrast, fractures observed in core indicate both brittle and ductile behaviour in response to compressive tectonic stress (Plate 21). Despite significant annealing in cataclastic zones, some good fracture porosity is preserved (Plate 21b, c).

The timing of fracture formation may be constrained using oxygen isotopic data from fracture cements and reasonable assumptions regarding the origin of these cements. Two sets of samples, consisting of fracture cement and host concretion calcite, were analyzed (Fig. 17). The difference in the $\delta^{18}\text{O}$ values of the host concretion and fracture cement calcite for both sets of samples is $\sim 10.2\text{\textperthousand}$. Utilizing calcite concretion $\delta^{18}\text{O}$ values and assuming an early diagenetic origin (3°C) for concretion calcite formation, calculated compositions of fluid from which concretions form are approximately $-7\text{\textperthousand}$ (Eq. 1, Fig. 32). If fracture-fill calcite is derived from the dissolution–precipitation of this early calcite, and fracture-fill cement is coeval with fracture formation, temperatures of between 40 and 50°C are indicated for fracture formation (Fig. 32). This suggests fracture formation at about 2.0 – 2.3 km of burial utilizing the present geothermal gradient for southwestern Alberta of $22^\circ\text{C}/\text{km}$ (Majorowicz et al., 1985) and assuming a 0°C surface temperature. The low temperature of fracture formation indicates fracture development before the onset of local oil generation, but fractures could develop updip of mature source rock and therefore contribute to hydrocarbon migration. Fracture formation would occur at higher temperatures if the surface temperature were higher. By the Early Tertiary, nonmarine sediments were being deposited over much of the Western Interior suggesting surface temperatures of $\sim 20^\circ\text{C}$.

The origin of the relatively enriched $\delta^{13}\text{C}$ values of the fracture-fill cement (Fig. 17) is not clear. The most likely source of $\delta^{13}\text{C}$ -enriched carbonate is from OM maturation. Both biogenic and thermogenic gas generation result in ^{13}C enrichment in the residual OM. Oxidation of this residual material would result in dissolved bicarbonate with relatively high $\delta^{13}\text{C}$ values. Other possible sources include Paleozoic formation waters that migrated updip, or infiltrating meteoric waters.

Summary paragenesis

A generalized paragenesis for Colorado Group shales is summarized in Figure 33. Pyrite, calcite concretions, and possibly early siderite concretion growth resulted primarily from bacterial sulfate reduction and possibly dissolved bicarbonate sourced from underlying sediments undergoing methanogenesis. Most siderite formed in response to methanogenic activity. The temperature near the sediment–water interface is calculated to be about 3°C . Early kaolinite and I/S authigenesis resulted from the alteration of volcanic ash and most likely lowered pore-water $\delta^{18}\text{O}$ values by up to $\sim 3\text{\textperthousand}$. Some illitization of I/S may have occurred in response to increased burial. Quartz, plagioclase and localized K-feldspar dissolution occurred with continuing burial. Fe-carbonate overgrowths on bioclastic grains are inferred to postdate significant pyrite and siderite concretion growth. Localized, intensive grain dissolution occurred near maximum burial depths, presumably because of the migration or expulsion of fluids. In the Second White Specks, fracture development occurred in response to tectonic stress at temperatures of about 50°C .

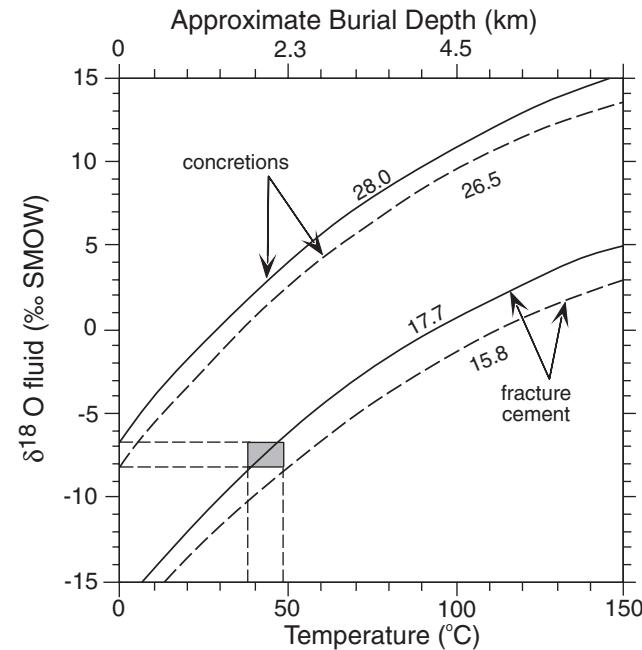

Figure 32. Temperature and approximate burial depth versus calculated $\delta^{18}\text{O}$ values for fluids from which authigenic carbonate may have precipitated for paired samples shown in Figure 17 using the geothermometer of Friedman and O’Neil (1977). Stippled box indicates inferred temperature range of formation temperature for fracture-fill calcite cement assuming recrystallization of primary calcite concretion carbonate. $\delta^{18}\text{O}$ values of the carbonate cements used in the calculations are indicated on each curve. Figure 33. Paragenetic summary of observed diagenetic processes.

SOURCE ROCK POTENTIAL

The evaluation of sedimentary source rocks has become an integral component of hydrocarbon exploration and basin analysis. Clastic source rocks are commonly fine grained (> 50% silt- or clay-sized material) and can be defined on the basis of their organic matter content with a minimum value of about 0.5 wt% (Tissot and Welte, 1984). In the context of basinal petroleum systems, source rocks may be further subdivided into three types: *possible source rock*, that is, a sedimentary rock that may have generated hydrocarbons but is not yet evaluated; *effective source rock*, one that has generated and expelled hydrocarbons; and *potential source rock*, an immature sedimentary rock that is capable of generating hydrocarbons (Waples, 1984).

Distribution of organic matter

The present distribution of organic matter (OM) within the Colorado Group is controlled by depositional facies and diagenetic processes, including maturation and migration. The distribution of OM (as TOC) is shown for each formation on a basinal scale in Figure 34. Because of the small number of data points for the Westgate, Fish Scales, and Belle Fourche formations, the isopleths in these (and subsequent) figures should be considered tentative. The type of OM is also useful in evaluating the distribution and maturation of OM, and the HI values for each formation are shown in Figure 35. In addition, selected vertical profiles for TOC and HI are shown in Figures 36 and 37. The cross-section locations are shown in Figure 2.

The Westgate and Belle Fourche formations show broad areas of constant TOC content of between 1.5 to 2.0 wt%. In the Westgate, there is a slight increase in TOC in southern Alberta (Fig. 34). This increase occurs with an increase in HI (Fig. 35) and reflects the anomalously high TOC and HI values within the Westgate that occur in the area just east of the disturbed belt in the Keho Lake area (Fig. 37). A similar pattern is seen in the Fish Scales Formation (Fig. 34, 35). The Belle Fourche Formation shows an increase in HI values in the same area but no discernible increase in TOC. All three formations show a southwest to northeast decrease in HI values away from the disturbed belt.

In contrast, the Second White Specks shows an increase in both TOC and HI to the northeast. Where the sediments are immature, these values are interpreted as reflecting increased marine organic productivity in the well-developed marine environment that existed in the basin during Second White Specks deposition (Cadrin, 1992; Bloch et al., 1993; Schröder-Adams et al., 1996). Second White Specks organic matter was deposited primarily under anoxic bottom waters. Lower TOC and HI values in the other formations reflect more proximal marine sediments deposited under more shallow-water conditions. These environments were less productive and bottom waters were dominantly dysaerobic.

Maturation patterns

Maturation, as indicated by the pyrolysis temperature of maximum hydrocarbon generation (T_{max}), generally

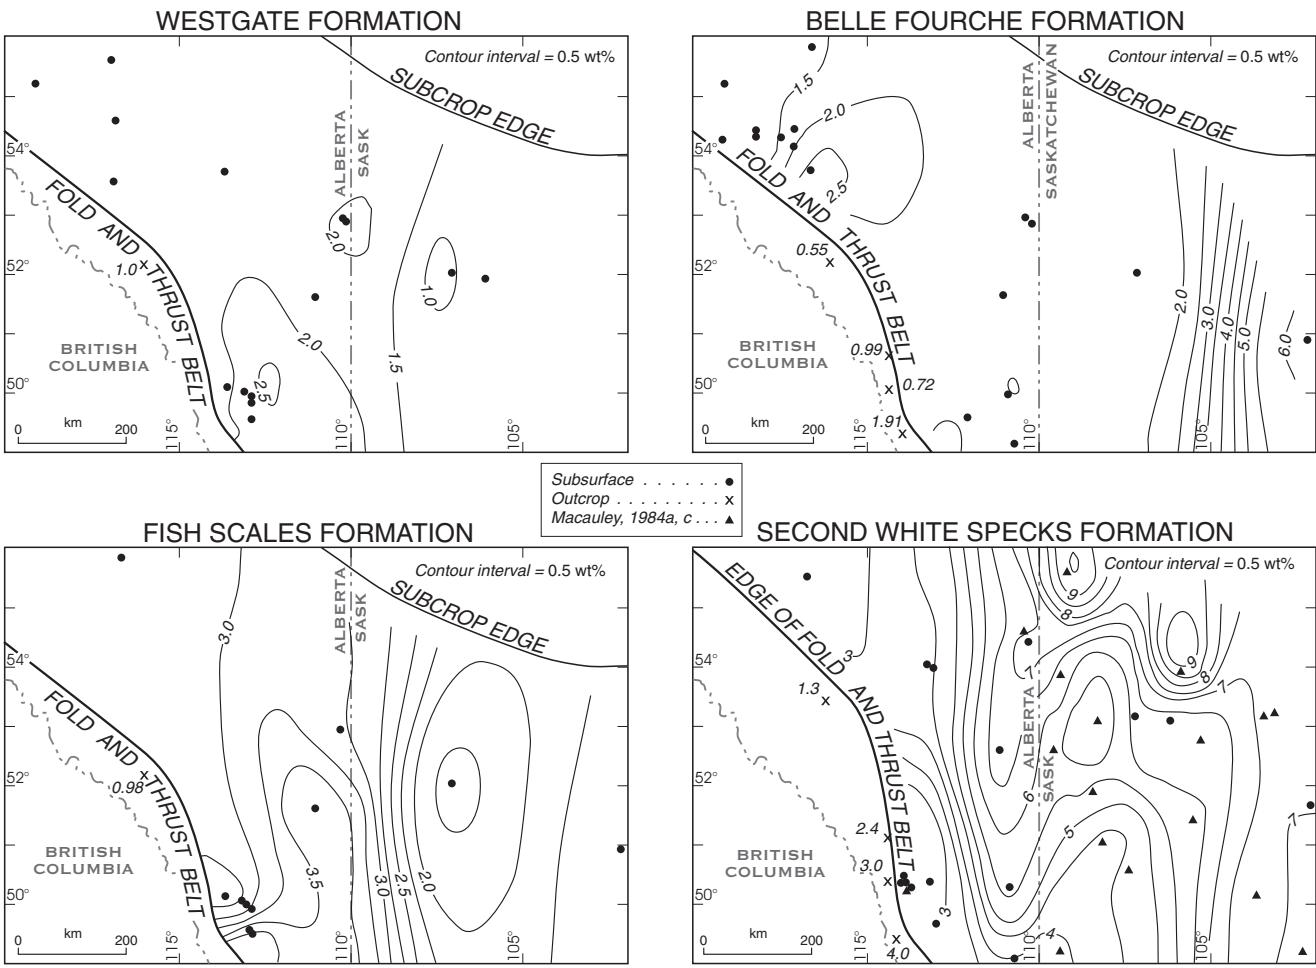

Figure 34. Contour maps of TOC (wt%) values for the four formations of the lower Colorado Group.

increases with depth (Fig. 38). Scatter in the data results from differential erosion during Tertiary uplift and variable mixtures of OM types. On a basinal scale, this translates into an east to west increase in maturation (Fig. 39). The onset of oil generation is generally considered to begin when T_{max} values reach 435°C (Tissot and Welte, 1984). This isotherm occurs at approximately 114° longitude in the Westgate and Belle Fourche formations and farther to the west, at about 115° longitude, for the Second White Specks. The data for the Fish Scales is too scattered to draw meaningful conclusions on a basinal scale, but in general, Fish Scales data are compatible with that from the other formations.

The occurrence of lower T_{max} values at equivalent depth in the Second White Specks suggests that oil generation may begin before the 435°C "threshold" is reached. Snowdon (1995) suggested that this "suppression" (lower T_{max} values at equivalent depth) may be related to a high sulphur content of the Second White Specks organic matter, similar to that documented in the Monterey Formation (Orr, 1986; Baskin and Peters, 1992; Zaback and Pratt, 1992). However, high

sulphur in organic matter has not been documented in the Second White Specks. Further, sulphur incorporation into organic matter during early diagenesis occurs in iron-limited sediments (Sinninghe Damste and de Leeuw, 1990) and the Second White Specks is generally not iron-limited (Bloch et al., 1993). T_{max} suppression in the Second White Specks may result from the absence of refractory Type III or IV organic matter, which has higher T_{max} values (Peters, 1986). The degree of mixing of OM types within the Second White Specks, and resulting maturation characteristics, are largely a function of depositional facies and may be extremely variable (Mösle, 1995). The "suppression" within the Second White Specks appears to be about 10°C (Fig. 38) and, if oil generation is occurring at lower temperatures, then a much larger volume of Second White Specks sediment is in the oil window (Fig. 39).

The basinal scale data do not show a rapid increase in maturation just to the east of the fold and thrust belt in southwestern Alberta. Here, T_{max} values may increase by 15 to 20°C over a lateral distance of approximately 50 km

(Fig. 40). Steep maturation gradients are present in this hinge zone because of the increased burial depth resulting from loading by the Rocky Mountains directly to the west. The tectonically induced plunge in this zone also increases the potential for fracturing (Mallory, 1977).

Depositional controls on hydrocarbon distribution

Where Colorado Group sediments are immature ($T_{max} < 435^{\circ}\text{C}$), the present distribution of OM is controlled by paleoenvironmental conditions and depositional processes. The entire Albian to Turonian interval east of approximately 114° longitude may be classified as potential source rock with significant internal variability. Isopleths generally trend north-south. This is, in part, an artifact of the location of the small number of sample control points that trend east-west. Additional data will undoubtedly complicate this simple picture. However, the north-south trends shown by the data are consistent with facies models of the Interior Seaway (Kauffman, 1977) that indicate a north-south strike for

basinal facies that, to a large degree, are parallel to paleoshorelines.

The persistence of low HI values in central Saskatchewan is suggestive of a paleohigh in that area. However, the increased thickness of the Westgate Formation in the C.M.S. Vanscoy well (11-16-35-8W3, Fig. 29) indicates a depocentre from which this formation thins both to the east and the west. The thinning of the overlying units (Fish Scales, Belle Fourche, and Second White Specks) in this well suggest localized uplift in this area that occurred sometime in the Late Albian. The Morden Formation is not present in this area, and the Santonian First White Speckled Shale lies unconformably upon the Second White Specks, resulting in the single Speckled Shale of central Saskatchewan (Caldwell et al., 1978). This stratigraphic package, in contrast to those to the east and west, suggests the development of a localized topographic high in central Saskatchewan that developed over perhaps 2 m.y. in the Late Albian. The cause of this apparent basin-floor uplift remains elusive, but recent work (Leckie et al., in press) has

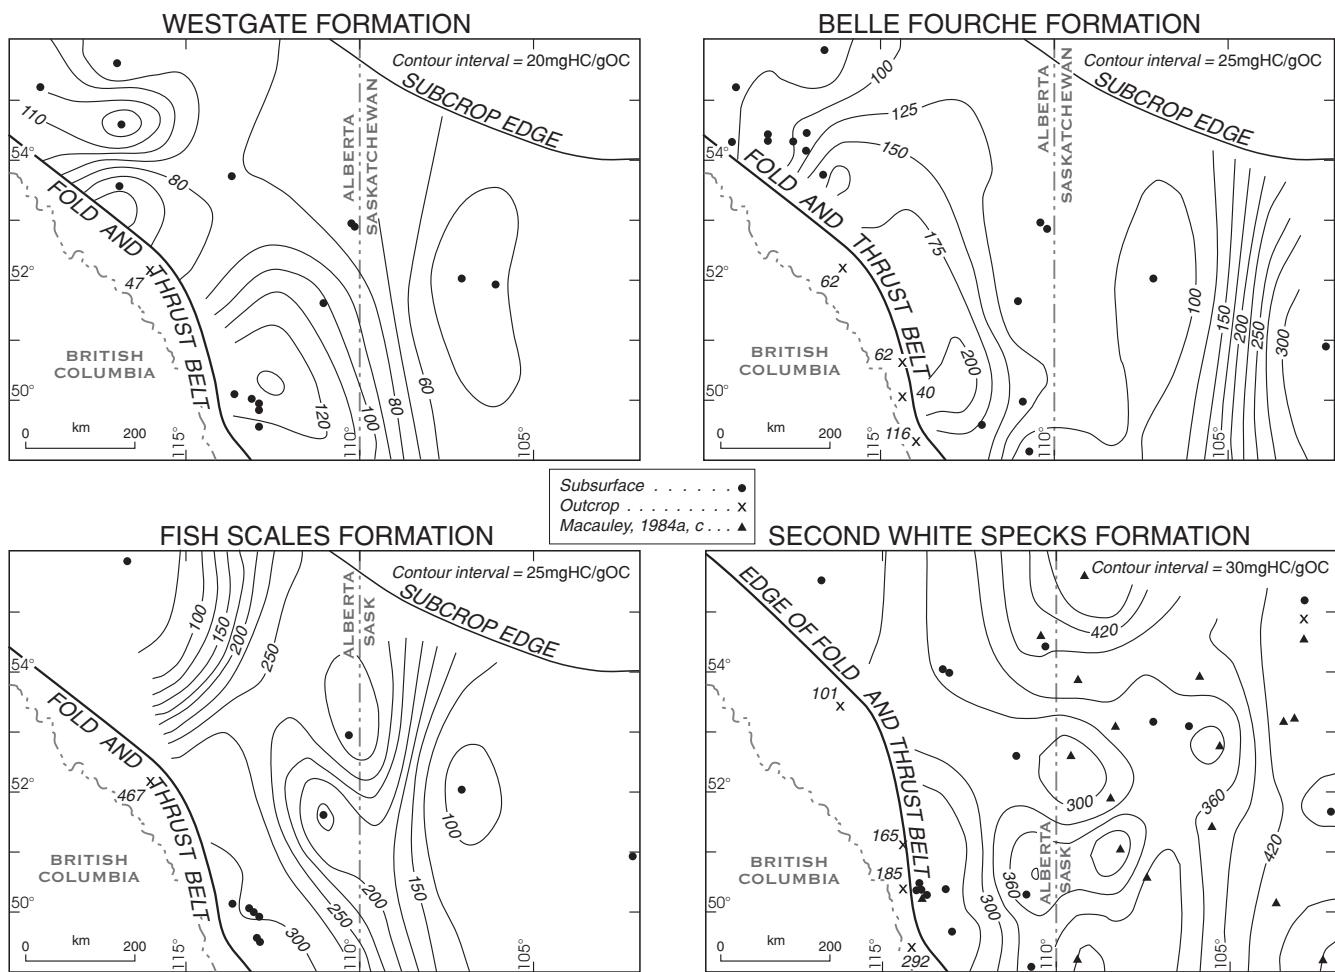

Figure 35. Contour maps of Hydrogen Index (mgHC/gOC) values for the four formations of the lower Colorado Group.

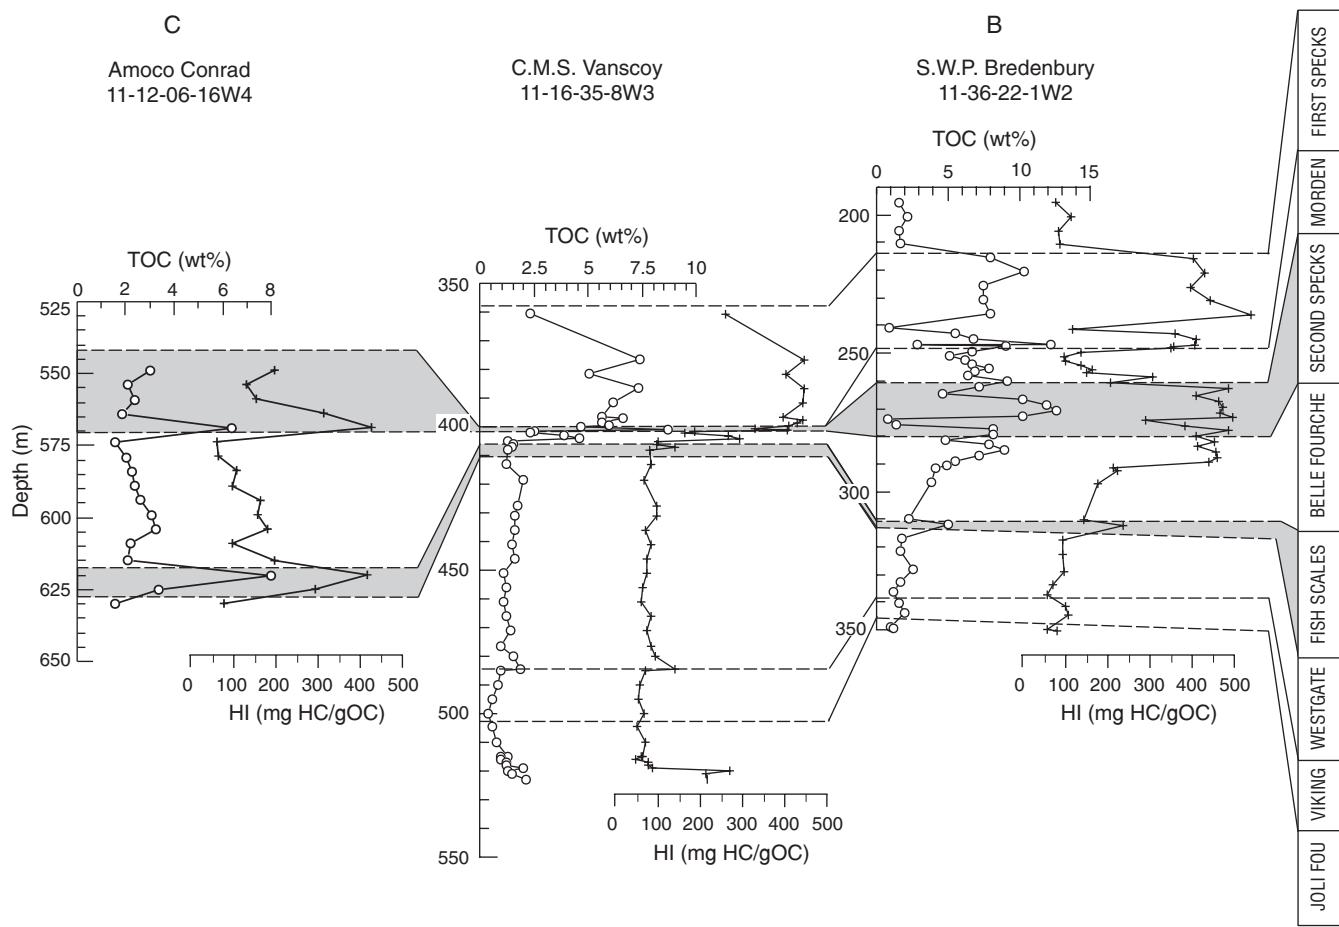

Figure 36. TOC and HI profile B-C (see Figure 2).

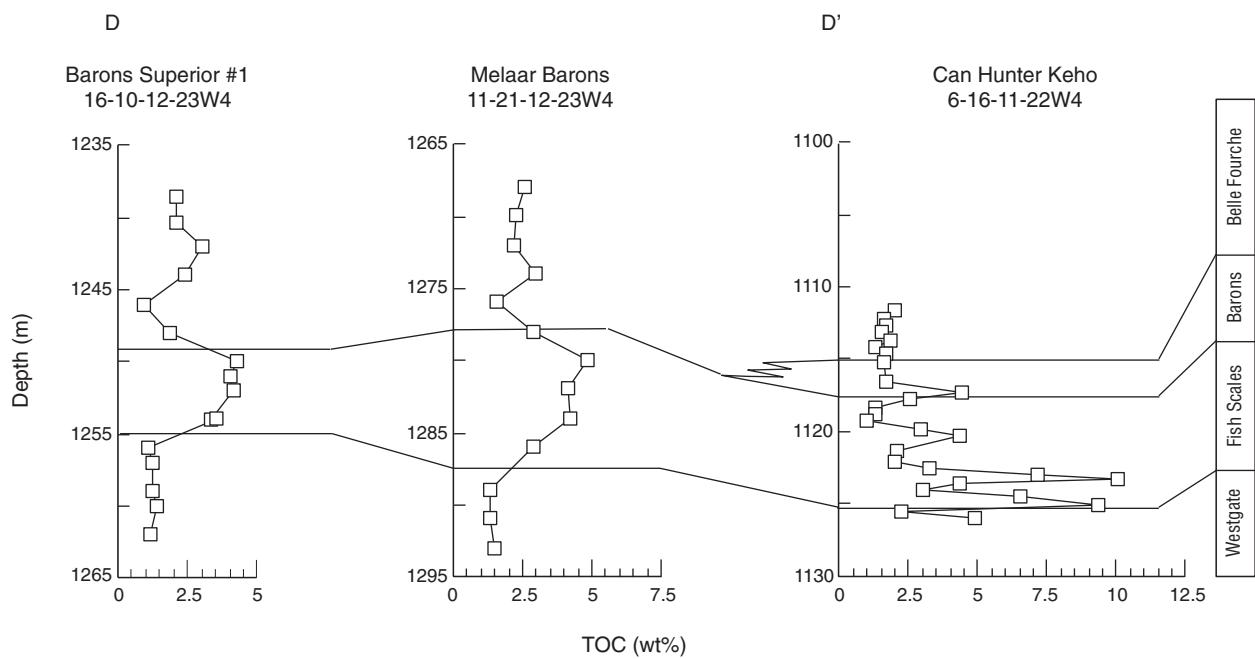

Figure 37. TOC and HI profile D-D' in the Keho Lake area of southwestern Alberta (see Figure 2).

documented the occurrence of kimberlites in central Saskatchewan that were emplaced at approximately 98 Ma. The complex internal geometry and compositional variability of this marine shale sequence indicate that the Cretaceous foreland basin was a dynamic depositional system and that source rocks may be much more heterogeneous than previously recognized.

The Second White Specks east of 114° longitude is a potential source rock and is the source of biogenic gas produced in some parts of southern Saskatchewan (Stasiuk and Goodarzi, 1988). The Westgate, Belle Fourche, and Fish Scales formations are also potential source rocks, but of a lesser quality. The greater abundance of Type III OM indicates that these formations are more gas prone.

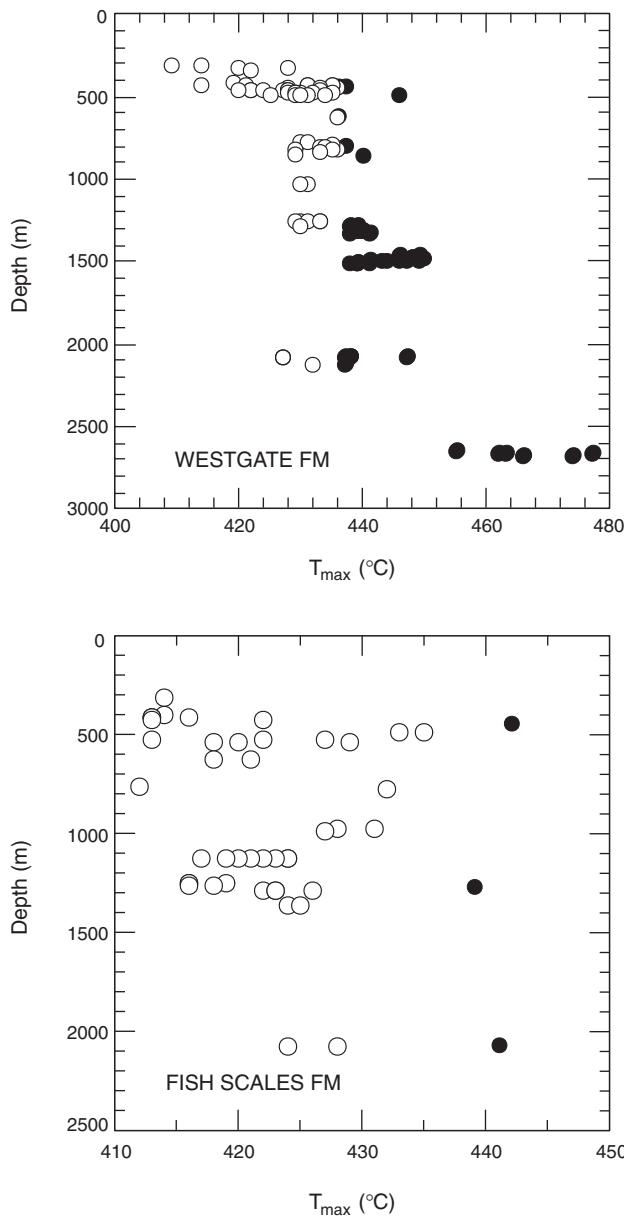

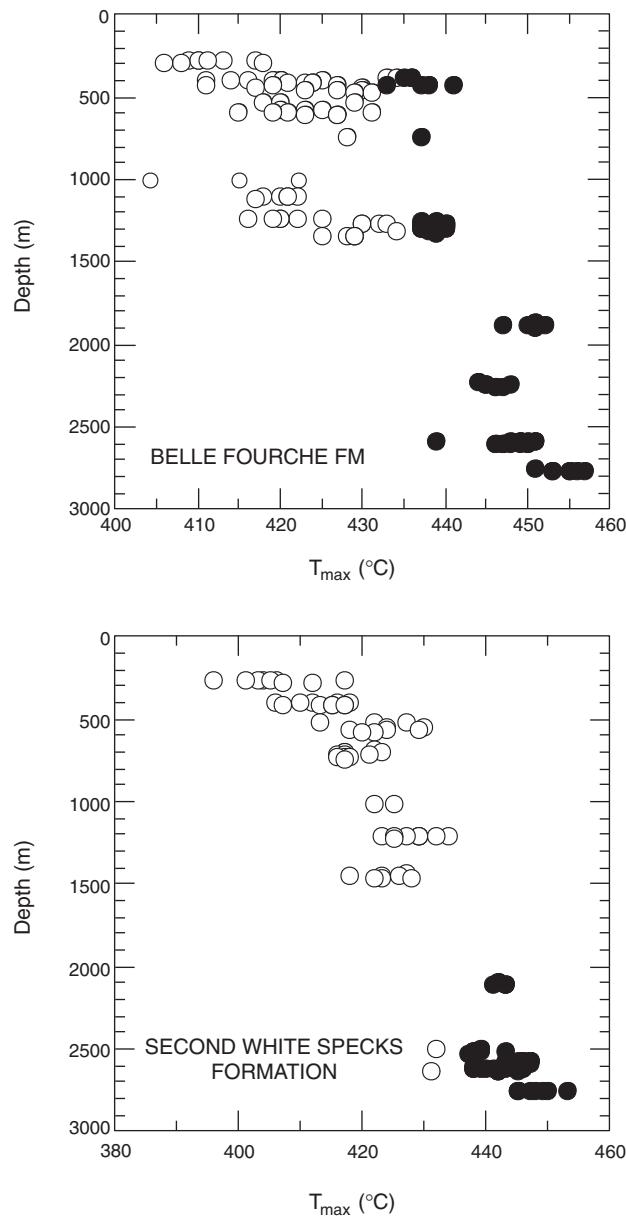

Figure 38. T_{max} versus depth for the four formations of the lower Colorado Group. Open circles are T_{max} values $<435^{\circ}\text{C}$; filled circles $>435^{\circ}\text{C}$ (see Table 2).

Maturation effects

Primary (depositional) heterogeneous OM distribution is affected by maturation and diagenetic overprinting west of 114° longitude. The ratio of volatile hydrocarbons to the total hydrocarbons ($S_1/(S_1+S_2)$) generated during pyrolysis, commonly called the production index (PI), provides information about the source of hydrocarbons within a sample and can discriminate between locally generated and migrated hydrocarbons or contamination.

Figures 41 to 44 show the PI ($S_1/(S_1+S_2)$) plotted against T_{max} and depth for the four formations. PI values between 0.1 and 0.4 generally define the zone of oil generation (Tissot and Welte, 1984; Peters, 1986). On a plot of PI versus T_{max} ,

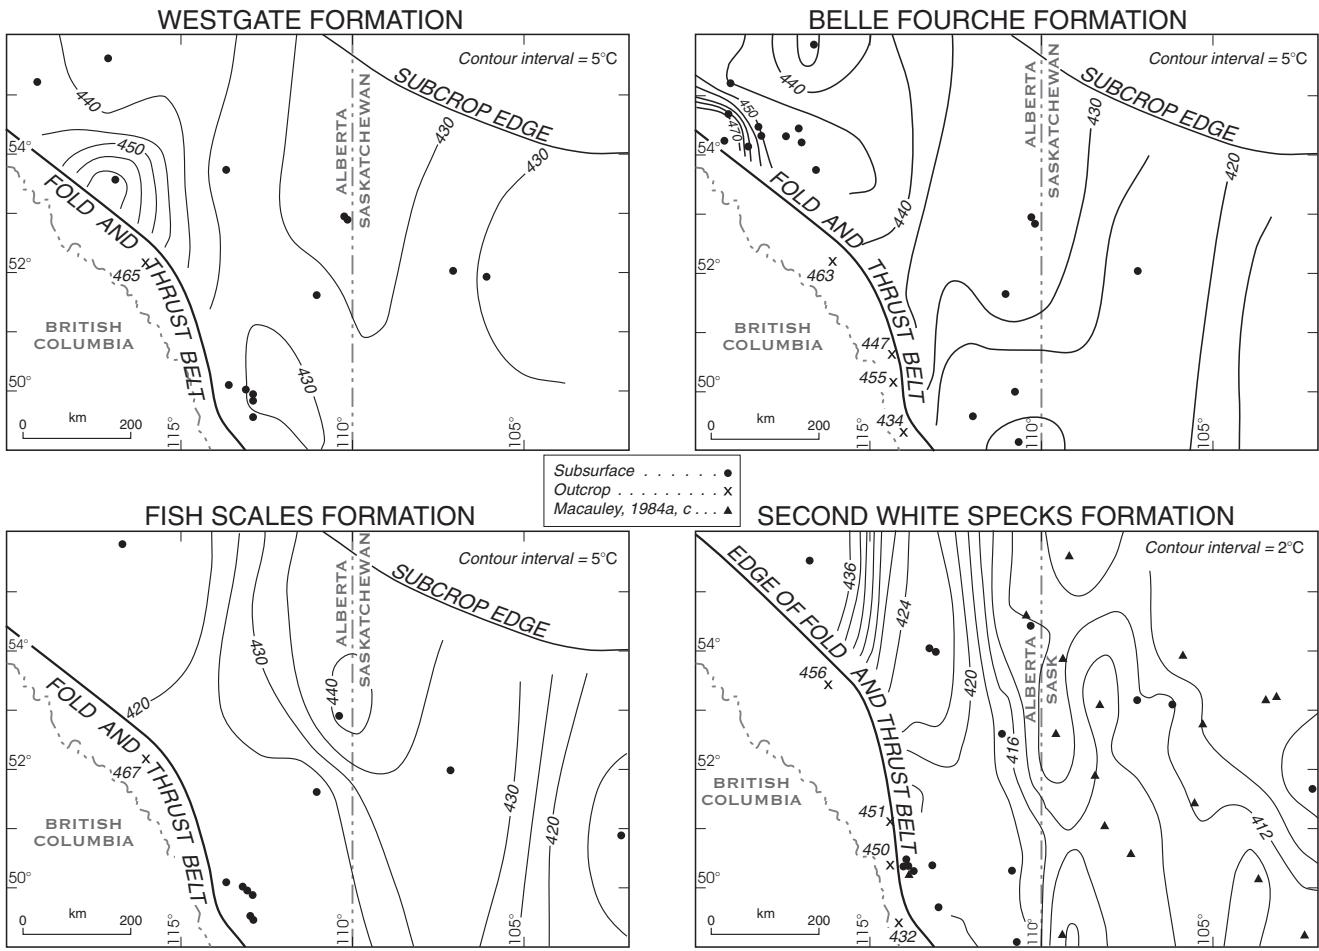

Figure 39. T_{\max} contour maps of the four formations of the lower Colorado Group.

immature samples will plot in an area confined by values of < 0.1 and 435°C , respectively, and mature samples will plot at greater values. The Belle Fourche (Fig. 43) and Second White Specks (Fig. 44) formations show this relationship fairly well. However, in the Westgate Formation, a large number of immature samples plot at PI values greater than 0.1 (Fig. 41). These samples either contain migrated hydrocarbons or are contaminated with drilling lubricants.

There are a large number of samples from the Amoco Youngstown B-1 (6-34-30-8W4) well (Table 1) at approximately 700 m depth in both the Westgate and Second White Specks formations that are contaminated with drilling lubricant. This is confirmed by GC-GCMS data (M. Fowler, pers. comm.). Within the Westgate Formation, the remainder of samples with T_{\max} less than 435°C and PI greater than 0.1 are primarily from two cores; the Anderson Husky Roros (10-35-45-2W4) and Imperial Kathleen #1 (5-1-77-20W5). In the case of the former, there is no evidence to suggest contamination and the high PI values are attributed to small amounts of migrated hydrocarbons. Many of these samples are from the basal Westgate and the hydrocarbons may have "leaked" up from the underlying Viking Formation. TOC

and HI values are slightly elevated in the basal Westgate (see Bloch et al., 1993; their fig. 10), consistent with this interpretation.

The samples from the Imperial Kathleen #1 well, spudded in 1951, are taken from 1 inch diamond drill core. Water-based drilling fluids were used and therefore the possibility of contamination by hydrocarbons is small, but cannot be completely ruled out. However, a nearby well (Imperial Wembley; see Table 1) contains OM that is marginally mature (T_{\max} to 440°C) with PI values to about 0.2. Together, these wells form a local trend distinct from other wells (Fig. 45) and suggest the presence of migrated hydrocarbons. The amount of migrated oil is small because the TOC (Fig. 34) and HI (Fig. 35) values show no significant increase from average formation values.

Immature samples at depths greater than 1000 m with PI values greater than 0.1 are also anomalous (Fig. 41). The presence of migrated hydrocarbons in mature samples lowers the T_{\max} value (Peters, 1986). These samples are from wells located just west of Keho Lake (see Fig. 2). In these cores, visible oil-staining has been documented, particularly

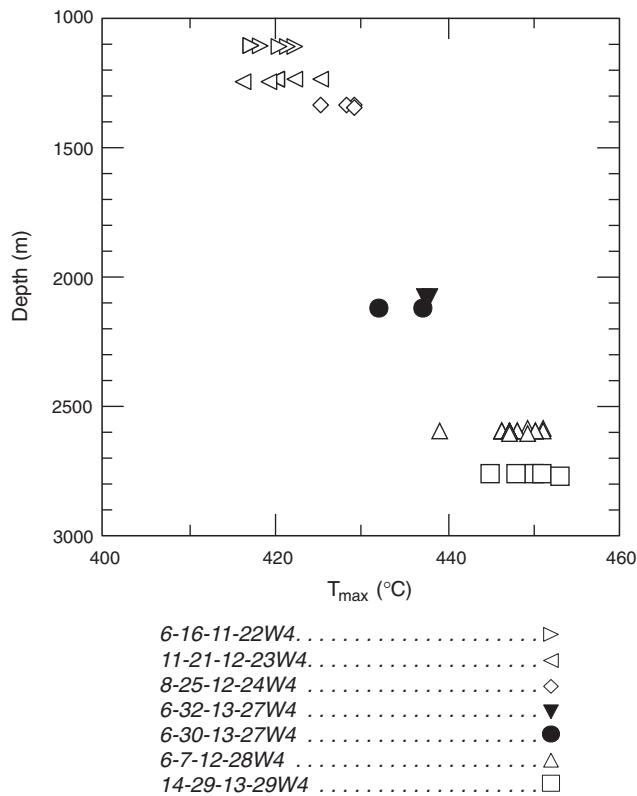

Figure 40. T_{\max} versus depth of Belle Fourche (open symbols) and Westgate (filled symbols) formations just west of the Keho Lake area (see Fig. 2 for location).

in the Fish Scales Formation. Samples from the same cores characterized as immature occur at depth in the Fish Scales (Fig. 42), Belle Fourche (Fig. 43), and Second White Specks (Fig. 44). These data are interpreted as representing the presence of pervasive migrated oil through the section. Anomalously high TOC and HI values in the Westgate (Fig. 37) further support this interpretation.

The presence of migrated hydrocarbons in the Keho Lake area, and perhaps in the extreme northwest of the study area, affects regional patterns of hydrocarbon distribution, as shown in the HI and, to a lesser extent, the TOC contour maps. The Westgate and Fish Scales TOC maps (Fig. 34) show slightly higher values, and the HI values show a marked increase towards the fold and thrust belt that centers on the Keho Lake area. This is opposite to "normal" source rock trends that show a depletion in TOC and HI values with increasing maturity (Burtner and Warner, 1984). This characteristic trend is seen to the west of the fold and thrust belt where there is a distinct south to north increase in maturity (Fig. 39). The Second White Specks shows a "normal" source rock trend, in contrast to the other formations (Fig. 34, 35), where areas of higher maturity show a loss in hydrocarbon abundance and quality.

The Second White Specks has been identified as an effective source rock (Macauley, 1984a; Brooks et al., 1991; Creaney and Allan, 1992) and the regional trends shown herein suggests hydrocarbon generation has occurred west of 114° longitude. The enhanced stratigraphic resolution employed in this study indicates that migrated hydrocarbons, perhaps sourced from the Second White Specks, have infiltrated other shale units of the Colorado Group. This infiltration is localized areally and stratigraphically, occurring primarily along contacts with more permeable, intercalated sandstones (Barons, Viking Formation) or in siltstone-rich horizons within the shales. The regional

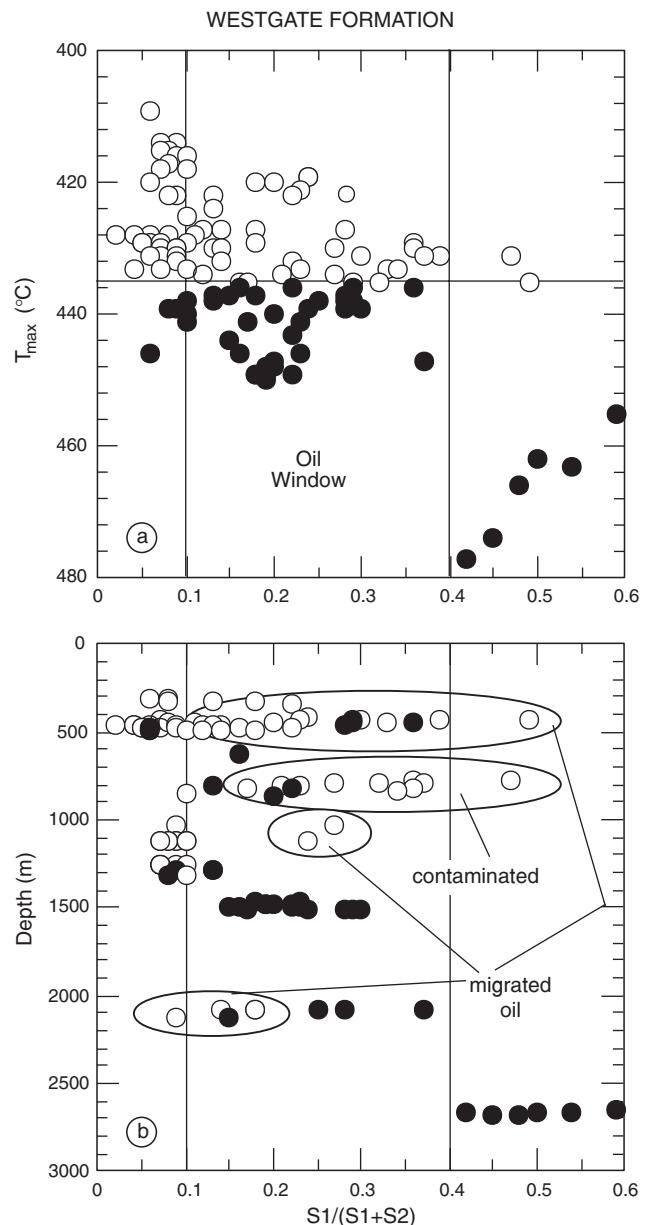

Figure 41. Production index ($S_1/(S_1 + S_2)$) versus T_{\max} (a) and depth (b) for the Westgate Formation. Open circles are T_{\max} values $< 435^{\circ}\text{C}$; filled circles $> 435^{\circ}\text{C}$ (see Table 2). See text for discussion.

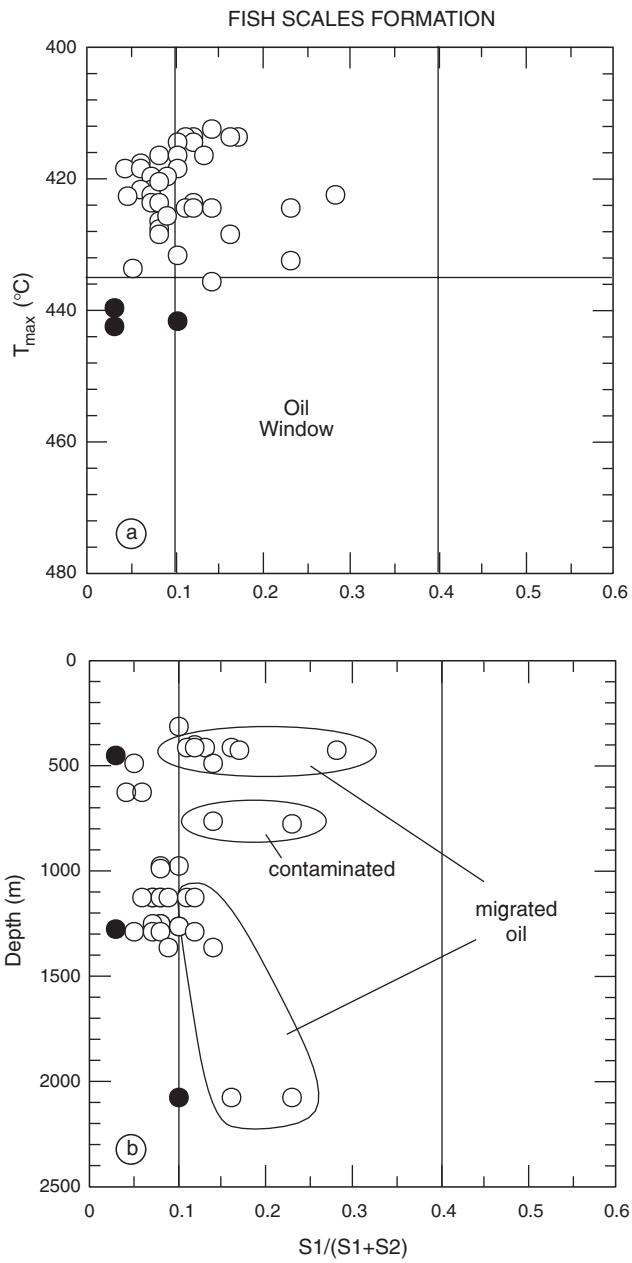

Figure 42. Production index ($S1/(S1+S2)$) versus T_{\max} (a) and depth (b) for the Fish Scales Formation. Open circles are T_{\max} values $< 435^\circ\text{C}$; filled circles $> 435^\circ\text{C}$ (see Table 2). See text for discussion.

patterns of hydrocarbon distribution indicate that migration has occurred, or is occurring, in the area west of Keho Lake and in northwestern Alberta on the southern flank of the Peace River Arch. Both of these areas are adjacent to the fold and thrust belt where maturation indices rapidly increase and most of the studied interval is within the oil window. The up-dip and cross-formation movement of evolved hydrocarbons within the Colorado Group is similar to other source rock studies that indicate source rock loss and

accumulation of hydrocarbons in more porous and permeable units of basin-fill sediments (Burtner and Warner, 1984; Hagen and Surdam, 1984). The localization of hydrocarbon migration argues against widespread fluid movement through thick sections of fine grained sediment with low porosity and poor permeability. The areas that apparently contain migrated hydrocarbons are within or adjacent to tectonically disturbed belts where rapid changes in plunge or areas of overthrusting are common. Fractures are also associated with these zones. Current production

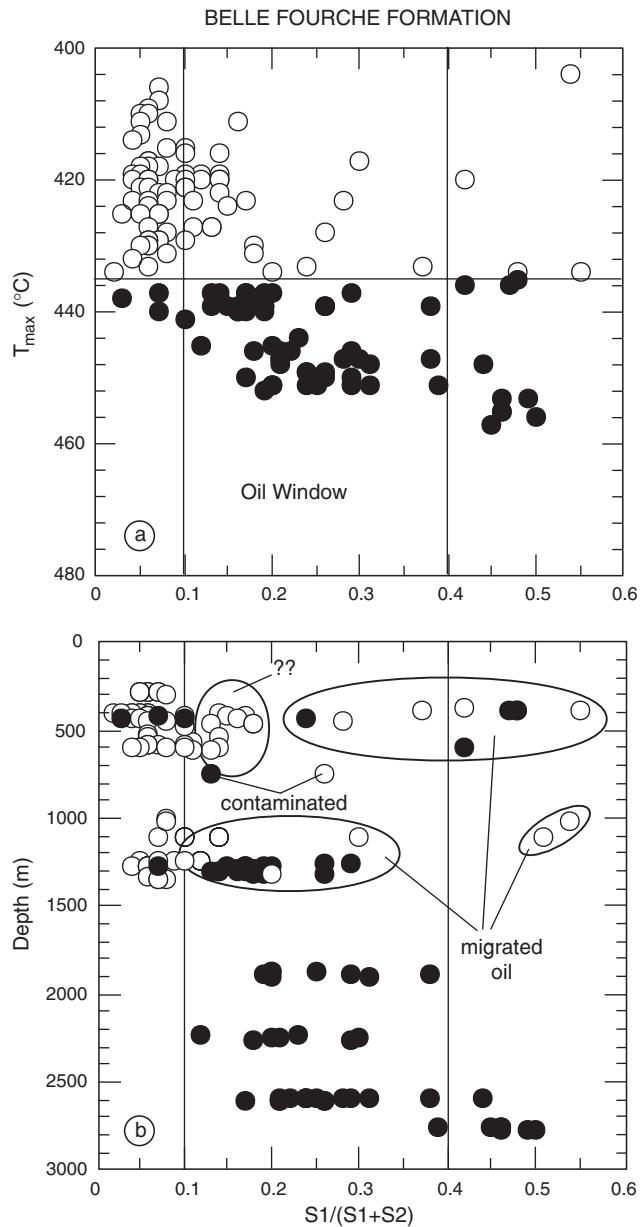

Figure 43. Production index ($S1/(S1+S2)$) versus T_{\max} (a) and depth (b) for the Belle Fourche Formation. Open circles are T_{\max} values $< 435^\circ\text{C}$; filled circles $> 435^\circ\text{C}$ (see Table 2). See text for discussion.

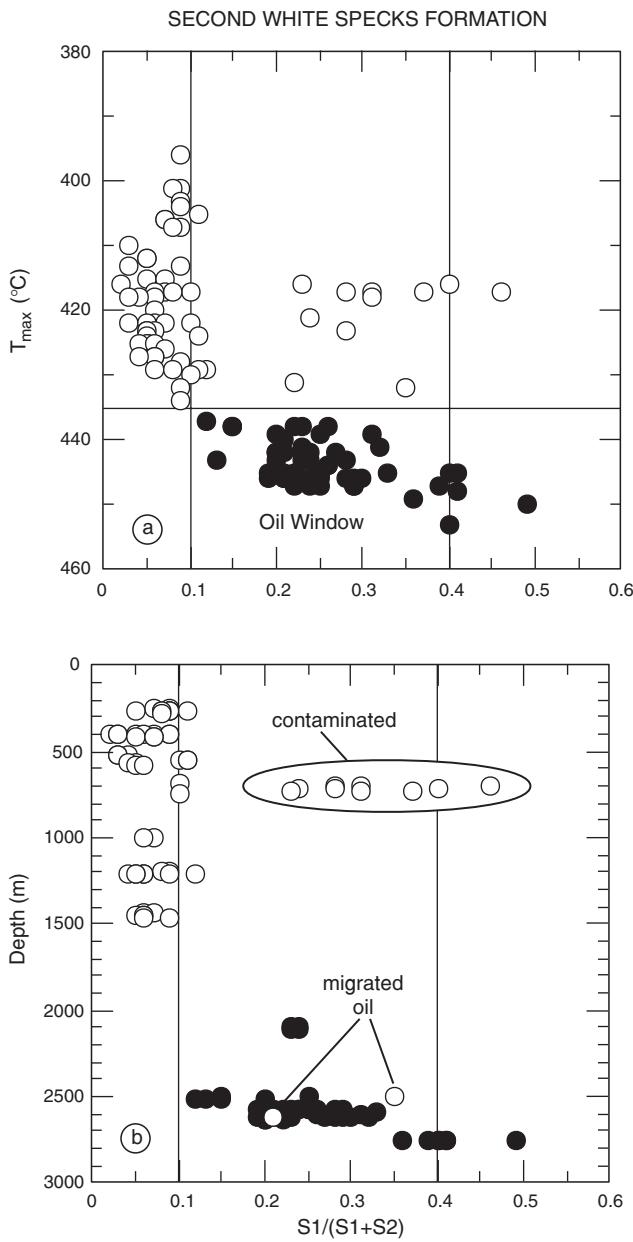

Figure 44. Production index ($S_1/(S_1+S_2)$) versus T_{\max} (a) and depth (b) for the Second White Specks Formation. Open circles are T_{\max} values $< 435^\circ\text{C}$; filled circles $> 435^\circ\text{C}$ (see Table 2). See text for discussion.

from Colorado Group shales occurs in areas adjacent to this zone where there is significant structural deformation of the basin-fill sediments (Portigal et al., 1989). These circumstances suggest a fracture control on the migration and production of hydrocarbons from the Second White Specks Formation.

RESERVOIR POTENTIAL

Source rocks may also be considered reservoirs when hydrocarbons are extracted from them directly. Biogenic gas is commonly extracted from potential source rocks. With advances in completion and extraction technology, some effective source rocks may also be economic liquid and gaseous hydrocarbon reservoirs (Mallory, 1977). Therefore, the study of source rock reservoir characteristics, analogous to traditional reservoir rock (sandstone and carbonates) studies, should also be included in basin analysis, petroleum system, and hydrocarbon exploration studies.

The low porosity and permeability of shales result from the high proportion of clay minerals and a dominantly matrix-supported fabric that compacts significantly, resulting in very poor reservoir properties. Therefore, economic production generally requires the occurrence of significant fracture porosity and permeability. To develop and sustain a fracture system, shales must behave in a brittle manner. Economically viable fractured shale reservoirs include the Mancos, Niobrara, and Mowry (Mallory, 1977),

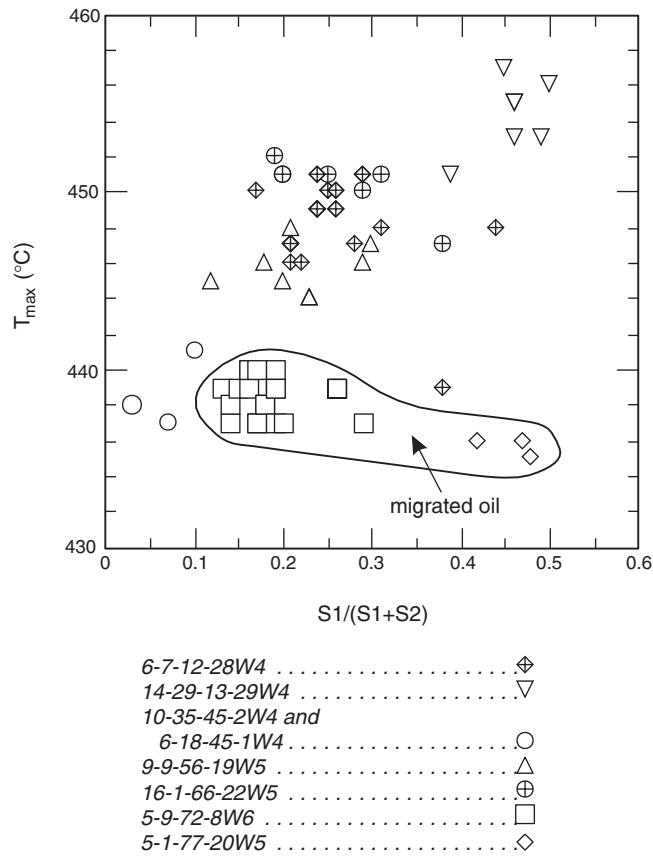

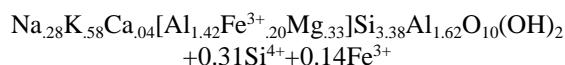

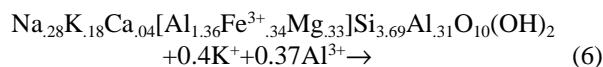

Figure 45. Production Index ($S_1/(S_1+S_2)$) versus T_{\max} for the Westgate Formation from selected wells.

Monterey (Graham and Williams, 1985), Bakken (Meissner, 1978), and Austin Chalk formations (Fritz et al., 1991). These units contain a high proportion of calcareous or siliceous material that imparts brittle characteristics to the rock. The only unit within the Colorado Group succession that contains considerable amounts of carbonate is the Second White Specks Formation (Table 9) and this unit is a proven producer (Portigal et al., 1989). Within the proposed stratigraphic nomenclature for the Colorado Group, considerable production identified to come from the "Second White Specks" actually comes from the siltstone interval in the uppermost Belle Fourche Formation. The relative importance of fracture porosity in production from calcareous and silt-rich intervals is not well understood but the variable and localized nature of "Second White Specks" production suggests that fracture porosity is a significant component. The distinct lithological (high proportion of quartz silt in the Belle Fourche) and mineralogical (calcareous nature of the Second White Specks) characteristics of the production interval within the Colorado Group suggest that mineralogy most likely is a factor in economic production from these units.

The relative effects of depositional and diagenetic controls on mineralogy and resulting rheological properties of Colorado Group shales are difficult to discern. Caritat et al. (1994a) demonstrated that diagenetic trends in mineralogy mimic depositional signals in the Belle Fourche Formation and this is probably applicable to other Colorado Group shale units. In the Belle Fourche, the illite content of I/S increases from east to west concomitant with an increase in maturity. However, the western portion of the basin is also the most proximal to the deltaic sediments of the equivalent Dunvegan Formation. These sediments are expected to contain a higher proportion of detrital illite as well as coarser grained quartz and feldspars. Therefore, depositional as well as diagenetic controls on mineralogy must be considered.

It is recognized from simple mass balance considerations that the formation of illite or illitic I/S from smectite or smectitic I/S results in the production of excess silica:

as shown by these mixed-layer clay compositions from the Belle Fourche Formation (Caritat et al., 1994a). This silica commonly precipitates as fine grained quartz within the matrix (see Caritat et al., 1994a; their fig. 10) or may contribute to quartz overgrowths that occur within the shale (Bloch and Hutzcheon, 1992). Other studies have suggested

that this silica is exported to adjacent sandstones where it may contribute to quartz cementation (Sibley and Blatt, 1976). The precipitation of authigenic quartz or quartz cement within the shale, however, will contribute to lithification and may enhance the brittle characteristics of the rock. This could be a factor in fracture formation within shales.

Some outcrop (Plate 19b) and core fracture surfaces show oil-staining. In outcrop, it is not clear whether the oil is locally sourced or migrated from downdip. In the subsurface, however, it is likely that fracture porosity is a critical component of liquid hydrocarbon migration and production in the Second White Specks Formation. It is also important to note that fracturing is observed only in areas where Colorado Group shales are considered mature (see below) and therefore have undergone a moderate to perhaps advanced degree of diagenetic alteration. The estimated depth (~ 2 km) and timing of fracture formation suggests that fractures developed before significant hydrocarbon generation or that fractures developed updip of mature source rocks. Fracture systems developing at this time could contribute to hydrocarbon migration and would provide storage capacity for generated hydrocarbons.

Appendix D

Dinoflagellate Plates

Plates A to D

(All figures x500)

Slides containing the figured dinoflagellates are curated in the type collection of the Geological Survey of Canada, Ottawa, Ontario but are currently located at the Geological Survey of Canada, Calgary, Alberta. For each specimen the GSC locality number (C-), palynology slide number (P) and GSC type number (GSC) are recorded. Stage coordinates and England Finder readings are on file with the specimens.

Plate A

- Figure 1. *Discorsia nanna* (Davey, 1974) Duxbury, 1977 C-167137, P3546-37b, GSC 103422
- Figure 2. *Protoellipsodinium spinocristatum* Davey and Verdier, 1971 C-167144, P3548-1c, GSC 103432
- Figure 3. *Wigginsiella grandstandica* Lucas-Clark, 1987 C-167144, P3548-1b, GSC 109902
- Figure 4. *Oligosphaeridium totum* Brideaux, 1971 C-167136, P3545-18b, GSC 109903
- Figure 5. *Ginginodinium evittii* Singh, 1983 C-167135, P3545-13f, GSC 109904
- Figure 6. *Ginginodinium evittii* Singh, 1983 C-167137, P3546-36b, GSC 103433
- Figure 7. *Fromea amphora* Cookson and Eisenack, 1958 C-167136, P3545-13e, GSC 109905
- Figure 8. *Ovoidinium verrucosum* (Cookson and Hughes, 1964) Davey, 1970 C-167137, P3546-36b, GSC 103425
- Figure 9. *Ovoidinium scabrosum* (Cookson and Hughes, 1964) Davey, 1970 C-167136, P3545-14d, GSC 112919
- Figure 10. *Pseudoceratium expolitum* Brideaux, 1971 C-167136, P3545-16b, GSC 112920
- Figure 11. *Catastomocystis spinosa* Singh, 1983 C-167144, P3548-1b, GSC 103440
- Figure 12. *Dingodinium cerviculum* Cookson and Eisenack, 1958; emend. Mehrotra and Sarjeant, 1984; emend. Khowaja-Ateequzzaman, 1990 C-167144, P3548-1c, GSC 103423
- Figure 13. *Gardodinium trabeculosum* (Gocht, 1959) Alberti, 1961 C-167144, P3548-1c, GSC 103424
- Figure 14. *Batioladinium jaegeri* (Alberti, 1961) Brideaux, 1975 C-167136, P3545-18b, GSC 112921
- Figure 15. *Odontochitina singhii* Morgan, 1980 C-167136, P3545-17b, GSC 112922
- Figure 16. *Hystrichosphaerina schindewolfi* Alberti, 1961 C-167135, P3544-6b, GSC 103420
- Figure 17. *Luxadinium propatulum* Brideaux and McIntyre, 1975 C-167136, P3545-17b, GSC 112923
- Figure 18. *Ascostomocystis gigantea* Singh, 1983 C-167136, P3545-15b, GSC 112924
- Figure 19. *Ascostomocystis maxima* Singh, 1971 C-167136, P3545-17b, GSC 112925

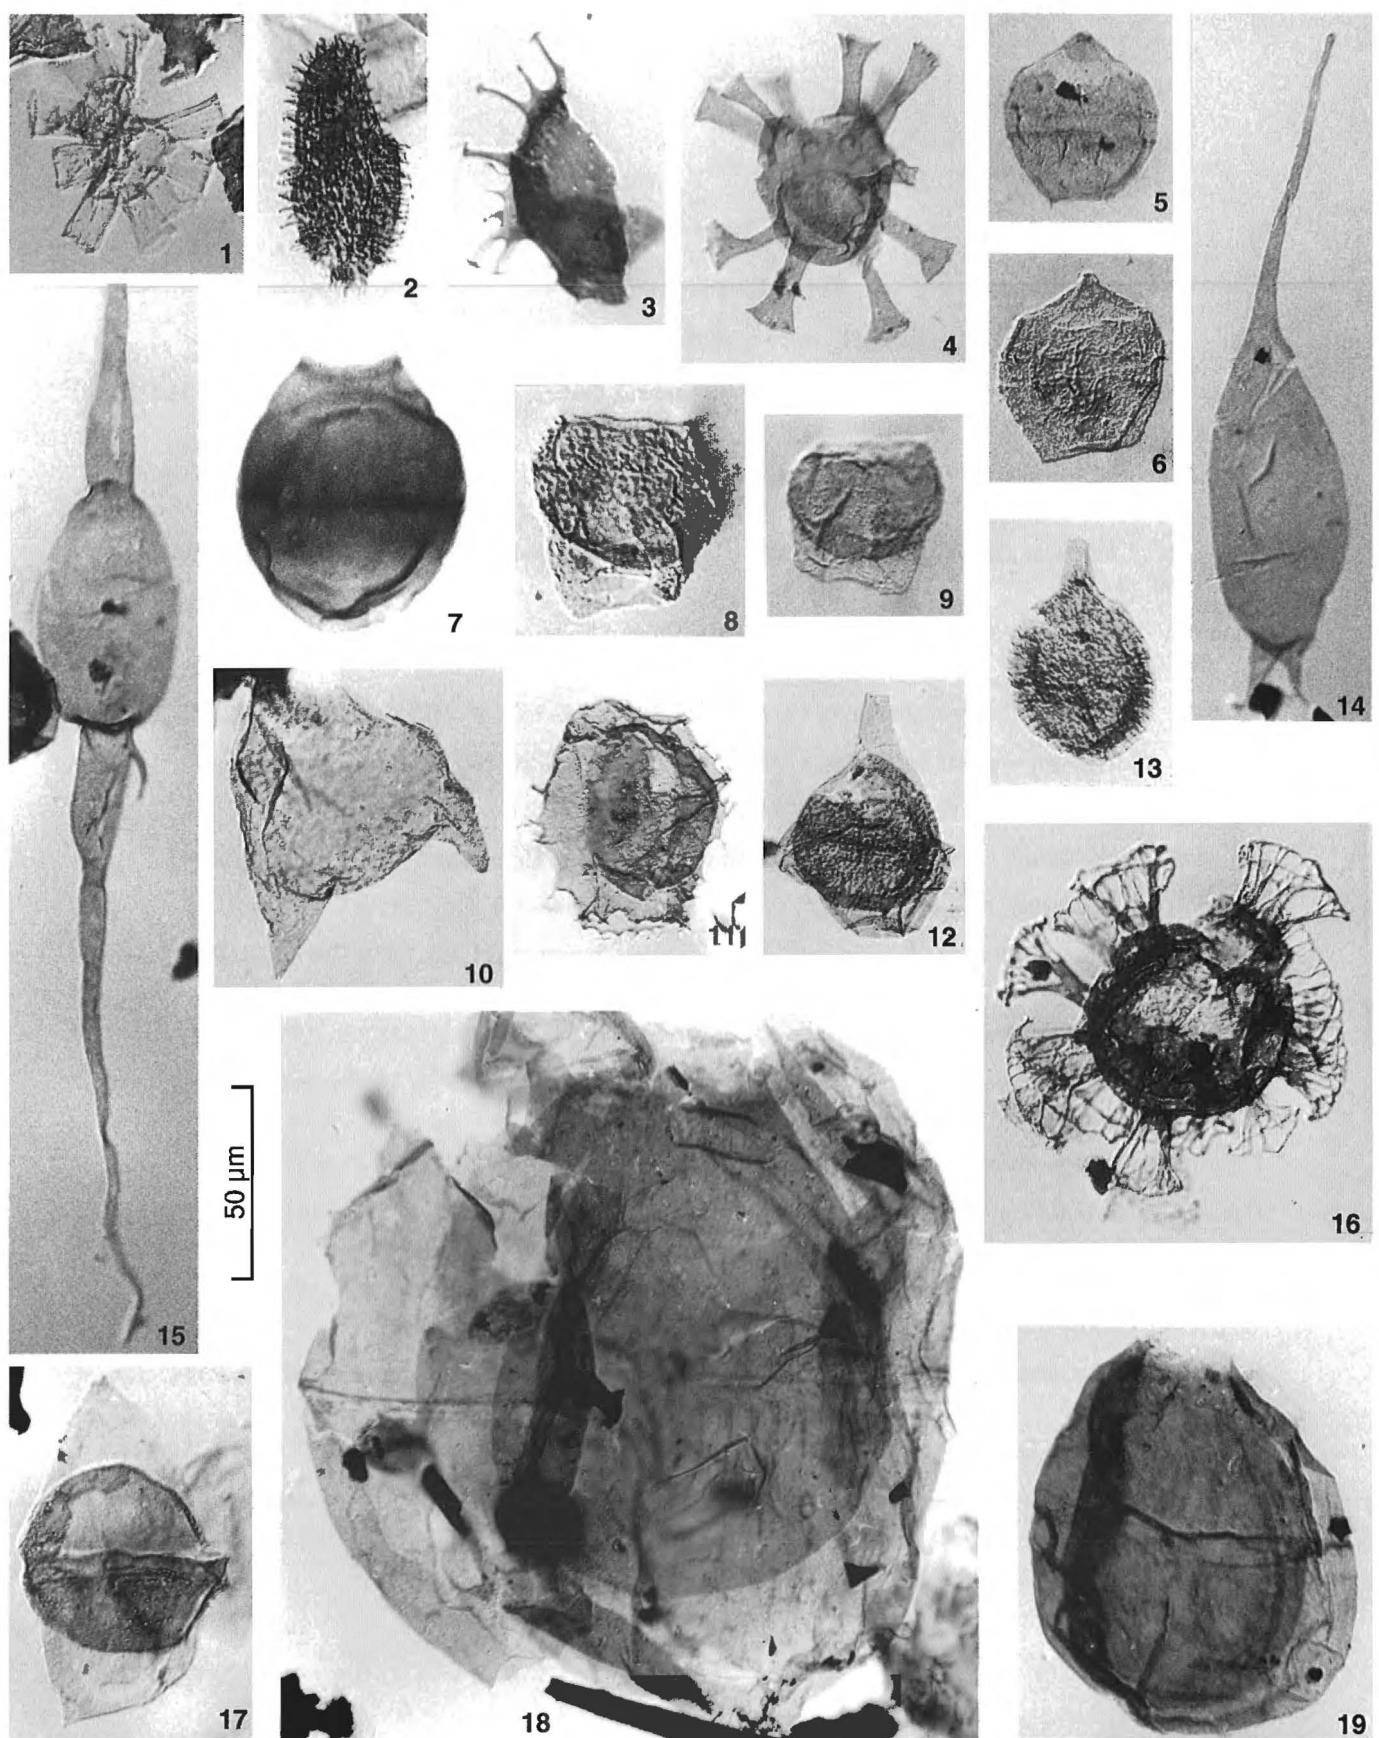

Plate B

- Figure 1. *Bourkidinium psilatum* Singh, 1983 C-167144, P3548-1b, GSC 103429
- Figure 2. *Palaeoperidinium cretaceum* Pocock, 1962 emend. Davey, 1970 emend. Harding, 1990 C-167136, P3545-14b, GSC 112926
- Figure 3. *Chichaouadinium vestitum* (Brideaux, 1971) Bujak and Davies, 1983 C-167137, P3546-37b, GSC 103421
- Figure 4. *Chichaouadinium vestitum* (Brideaux, 1971) Bujak and Davies, 1983 C-167144, P3548-1c, GSC 112927
- Figure 5. *Fromea fragilis* (Cookson and Eisenack, 1962) Stover and Evitt, 1978 C-167136, P3545-18b, GSC 112928
- Figure 6. *Florentinia cooksoniae* (Singh, 1971) Duxbury, 1980 C-167136, P3545-15b, GSC 112929
- Figure 7. *Florentinia verdieri* Singh, 1983 C-167144, P3548-1b, GSC 103434
- Figure 8. *Alterbidinium* sp. C-167144, P3548-1b, GSC 112930
- Figure 9. *Stephodinium australicum* Cookson and Eisenack, 1962 C-167136, P3545-17b, GSC 103435
- Figure 10. *Apteodinium reticulatum* Singh, 1971 C-167136, P3545-21b, GSC 112931
- Figure 11. *Cribroperidinium exilicristatum* (Davey, 1969) Stover and Evitt, 1978 C-167136, P3545-14b, GSC 112932
- Figure 12. *Pseudoceratium eisenackii* (Davey, 1969) Bint, 1986 C-167136, P3545-22b, GSC 112933
- Figure 13. *Oligosphaeridium pulcherrimum* (Deflandre and Cookson, 1955) Davey and Williams, 1966 C-167136, P3545-15b, GSC 112934
- Figure 14. *Cribroperidinium intricatum* Davey, 1969 C-167136, P3545-15b, GSC 112935
- Figure 15. *Ovoidinium verrucosum* (Cookson and Hughes, 1964) Davey, 1970 C-167136, P3545-11e, GSC 112936
- Figure 16. *Oligosphaeridium complex* (White, 1842) Davey and Williams, 1966 C-167136, P3545-15b, GSC 112937
- Figure 17. *Cribroperidinium edwardsii* (Cookson and Eisenack, 1958) Davey, 1969 C-167136, P3545-14b, GSC 112938
- Figure 18. *Nyktericysta* sp. C-167136, P3545-17b, GSC 112939
- Figure 19. *Limbicysta octoppediformis* MacRae et al., 1996 C-167136, P3545-10b, GSC 112940

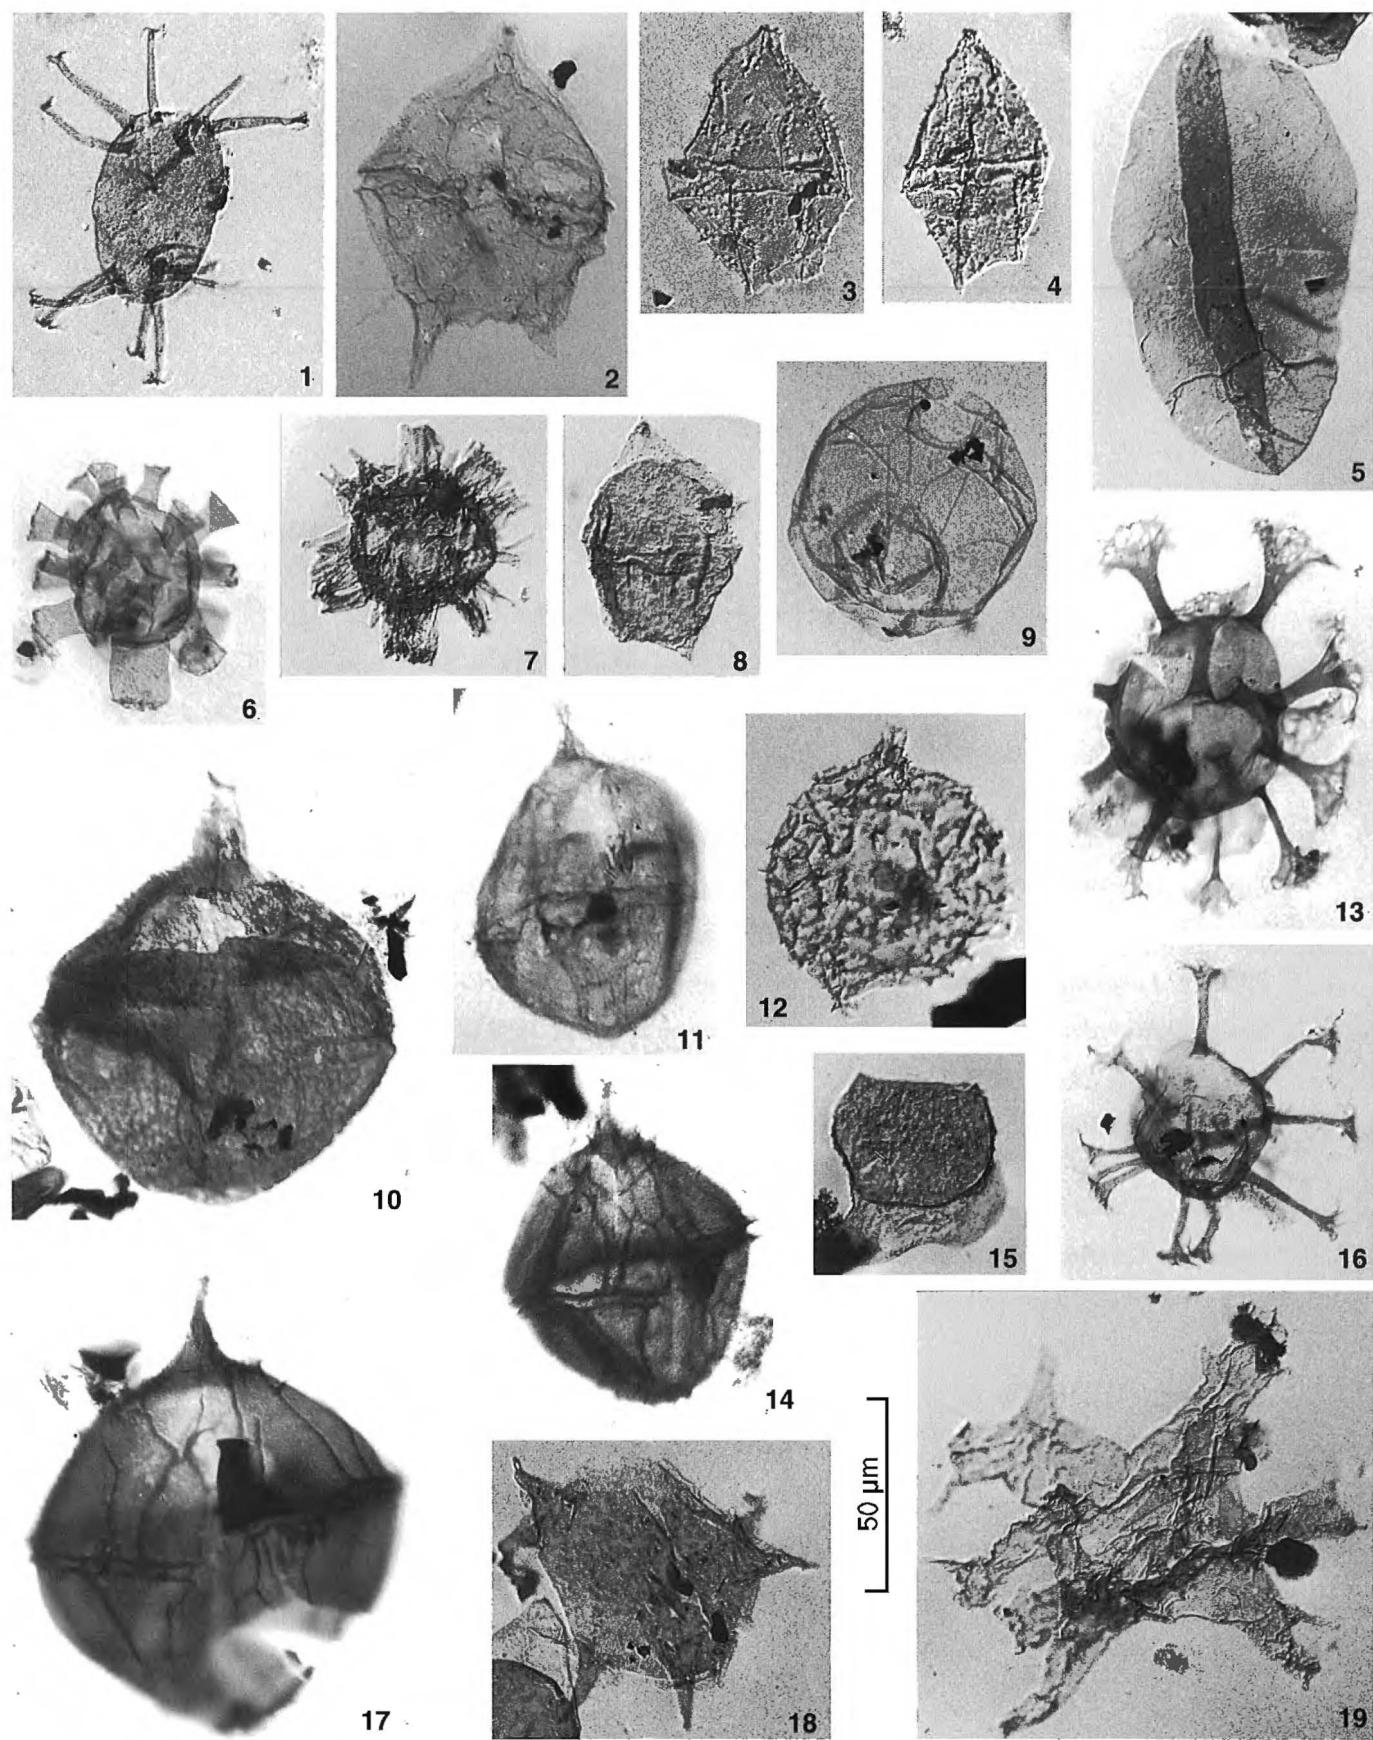

Plate C

Figure 1. *Odontochitina operculata* (Wetzel, 1933) Deflandre and Cookson, 1955 C-167136, P3545-12e, GSC 112941

Figure 2. *Odontochitina singhii* Morgan, 1980 C-167135, P3544-3b, GSC 112942

Figure 3. *Florentinia cooksoniae* (Singh, 1971) Duxbury, 1980 C-167136, P3545-12e, GSC 112943

Figure 4. *Trichodinium spinosum* Singh, 1971 C-167136, P3545-11e, GSC 112944

Figure 5. *Leberidocysta defloccata* (Davey and Verdier, 1973) Stover and Evitt, 1978 C-167136, P3545-12e, GSC 112945

Figure 6. *Isabelidinium magnum* (Davey, 1970) Stover and Evitt, 1978 C-167146, P3550-1a, GSC 103438

Figure 7. *Ascostomocystis gigantea* Singh, 1983 C-167144, P3548-1b, GSC 112946

Figure 8. *Pseudoceratium* sp. C-167136, P3545-12e, GSC 114450

Figure 9. *Eurydinium glomeratum* (Davey, 1970) Stover and Evitt, 1978 C-167146, P3550-2b, GSC 103439

Figure 10. *Eurydinium glomeratum* (Davey, 1970) Stover and Evitt, 1978 C-167146, P3550-2b, GSC 114451

Figure 11. *Alterbidinium "daveyi"* Stover and Evitt, 1978 C-167136, P3545-8e, GSC 114452

Figure 12. *Wallodinium luna* (Cookson and Eisenack, 1960) Lentin and Williams, 1973 C-167136, P3545-8e, GSC 114453

Figure 13. *Isabelidinium magnum* (Davey, 1970) Stover and Evitt, 1978 C-167136, P3545-7e, GSC 114454

Figure 14. *Leberidocysta defloccata* (Davey and Verdier, 1973) Stover and Evitt, 1978 C-167136, P3545-5e, GSC 114455

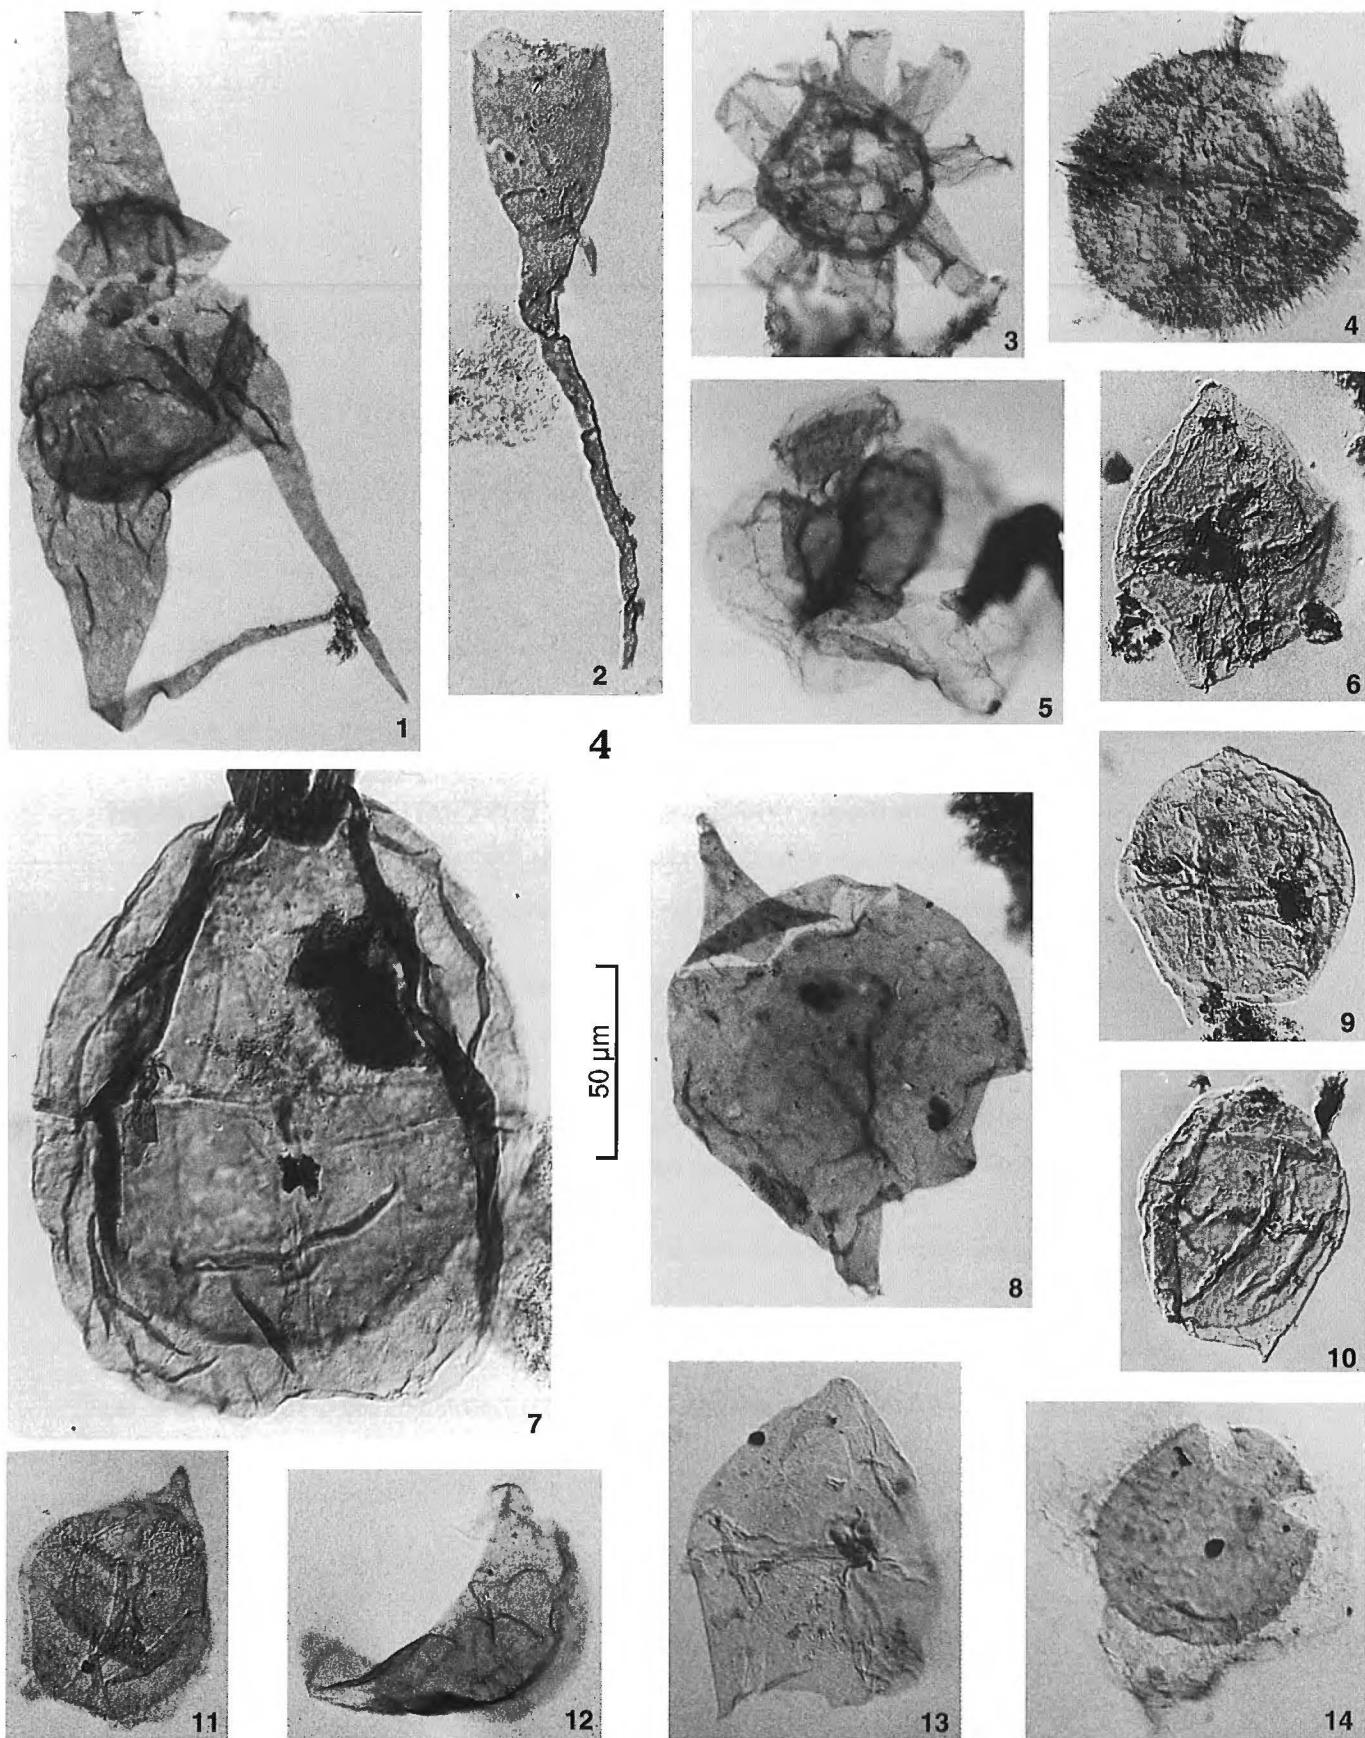

Plate D

Figure 1. *Kallosphaeridium ringnesiorum* (Manum and Cookson, 1964) Helby, 1987 C-167136, P3545-5e, GSC 114456

Figure 2. *Chatangiella granulifera* (Manum, 1963) Lentin and Williams, 1976 C-167136, P3545-1e, GSC 114457

Figure 3. *Chatangiella granulifera* (Manum, 1963) Lentin and Williams, 1976 C-167136, P3545-2e, GSC 114458

Figure 4. *Chatangiella ditissima* (McIntyre, 1975) Lentin and Williams, 1976 C-167136, P3545-1e, GSC 114459

Figure 5. *Isabelidinium globosum* (Davey, 1970) Lentin and Williams, 1977 C-167136, P3545-1e, GSC 114460

Figure 6. *Isabelidinium globosum* (Davey, 1970) Lentin and Williams, 1977 C-167136, P3545-1e, GSC 114461

Figure 7. *Eurydinium glomeratum* (Davey, 1970) Stover and Evitt, 1978 C-167136, P3545-5e, GSC 114462

Figure 8. *Trithryodinium dubium* Singh, 1983 C-167136, P3545-8e, GSC 114463

Figure 9. *Surculosphaeridium longifurcatum* (Firton, 1952) Davey et al., 1956 C-167136, P3545-8e, GSC 114464

Figure 10. *Dorocysta litotes* Davey, 1970 C-167136, P3545-4e, GSC 114465

Figure 11. *Trigonopyxidia ginella* (Cookson and Eisenack, 1960) Downie and Sarjeant, 1965 C-167136, P3545-2e, GSC 114466

Figure 12. *Dinopterygium cladoides* Deflandre, 1935 C-167136, P3545-8e, GSC 114467

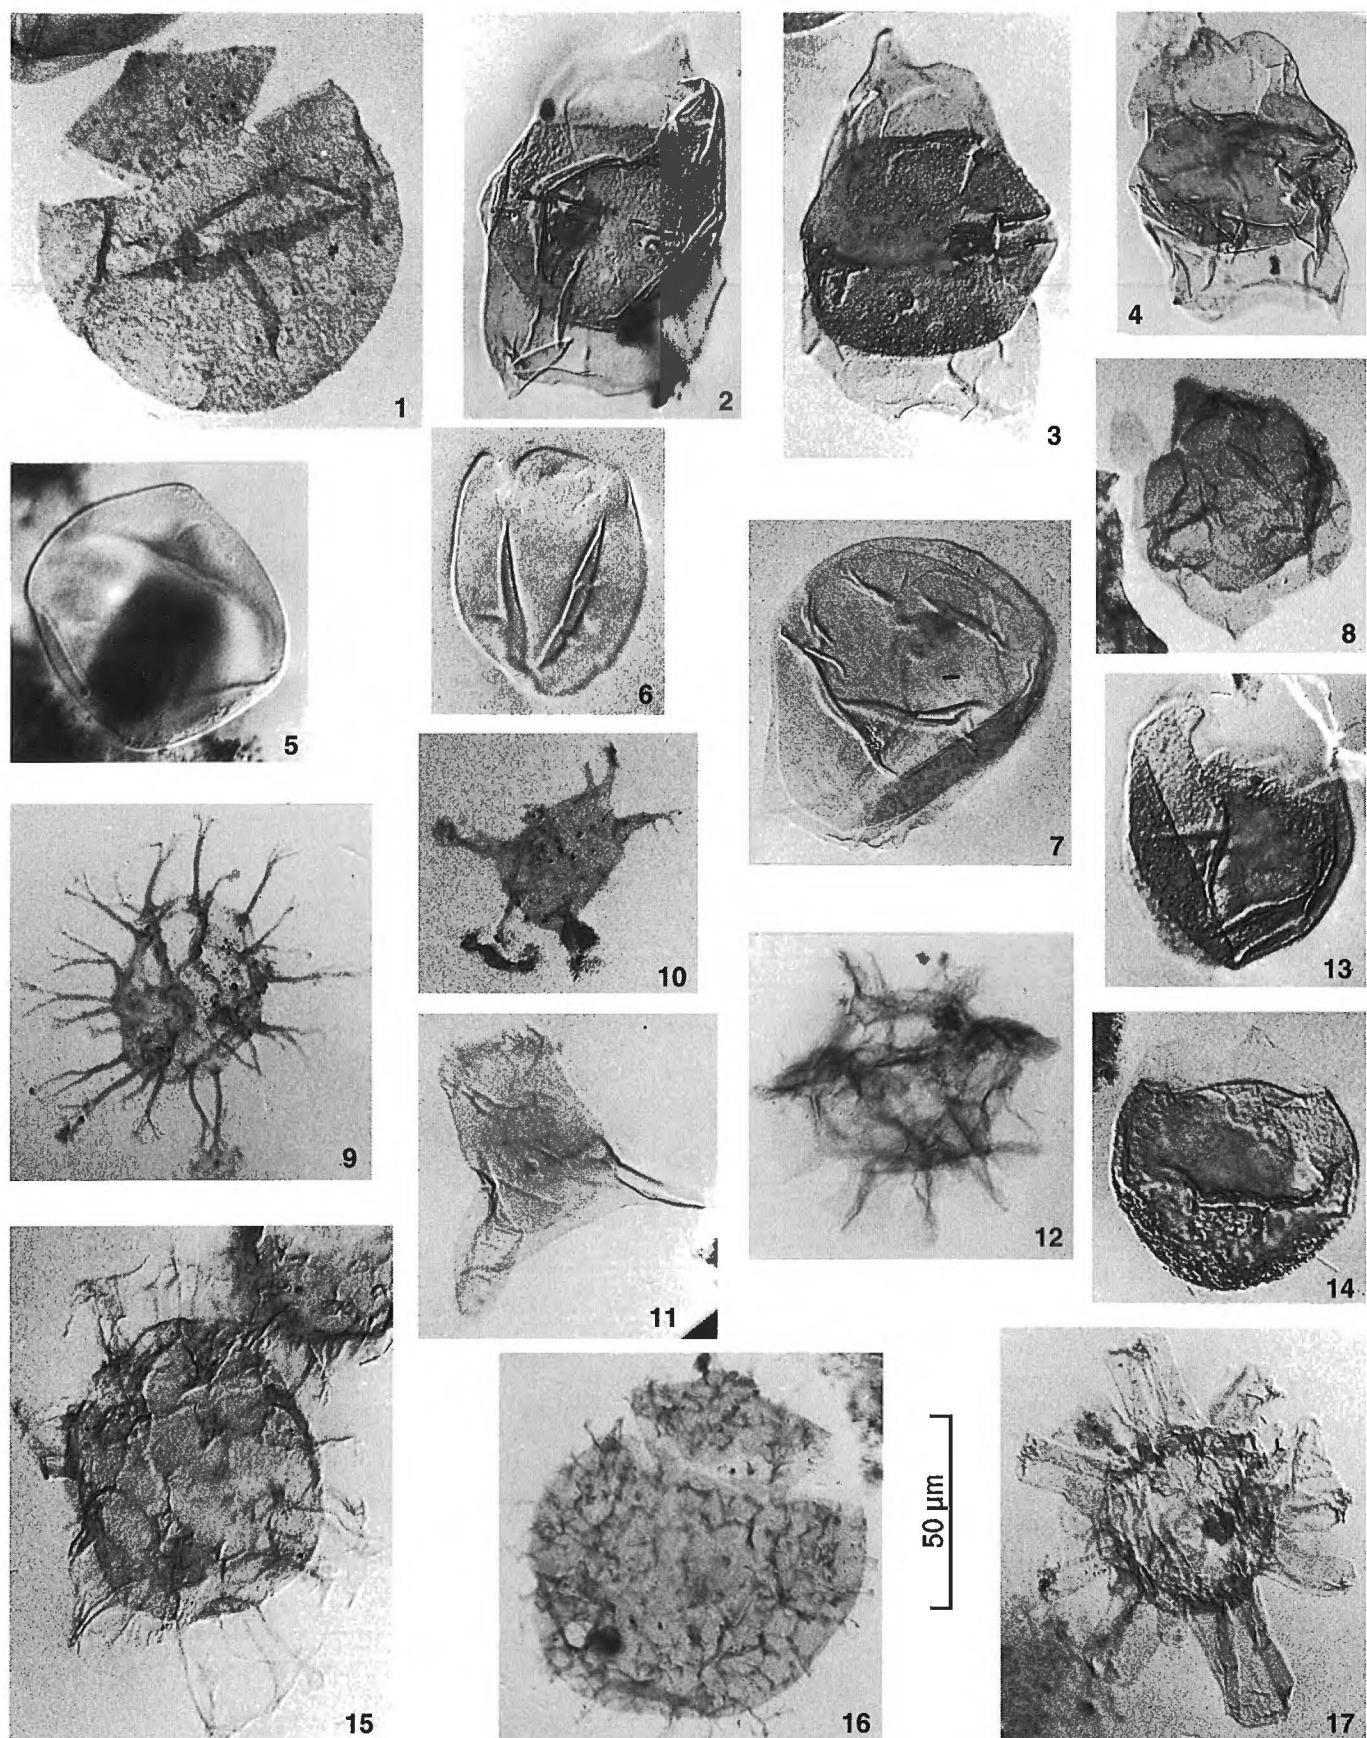

Figure 13. *Trithyrodinium suspectum* (Manum and Cookson, 1964) Davey, 1969 C-167136, P3545-2e, GSC 114468

Figure 14. *Trithyrodinium suspectum* (Manum and Cookson, 1964) Davey, 1969 C-167136, P3545-2e, GSC 114469

Figure 15. *Heterosphaeridium difficile* (Manum and Cookson, 1964) Ioannides, 1986 C-167136, P3545-2e, GSC 114470

Figure 16. *Circulodinium distinctum* (Deflandre and Cookson, 1955) Jansonius, 1986 C-167136, P3545-8e, GSC 114471

Figure 17. *Florentinia cooksoniae* (Singh, 1971) Duxbury, 1980 C-167136, P3545-2e, GSC 114472

Petrographic and foraminiferal plates

Plate 1

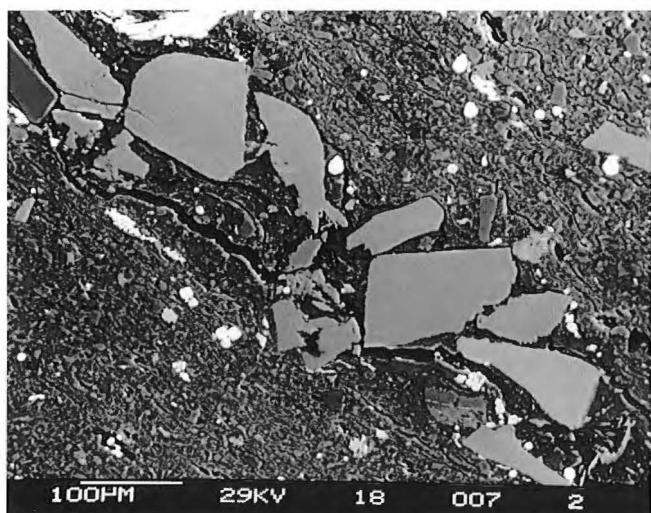

BSEM photomicrographs. GSC # = Geological Survey of Canada, Calgary photographic file number; # followed by six digits = sample number. Westgate Formation **a**) siltstone laminae overlain by a claystone laminae. Arrow indicates contact (#111618, 484.3 m - GSC #4072-77). **b**) matrix-supported fabric with quartz (q) and kaolinized biotite (arrow) (#111618, 484.3 m - GSC #4072-81). **c**) sand-sized K-feldspar grains in laminae of a starved ripple (#111618, 484.3 m - GSC #4072-78). **d**) K-feldspar (K), microcline (M), biotite (B), quartz (Q), and zircon (Z) in a sandy laminae (#111618, 484.3 m - GSC #4072-85). **e**) argillaceous rock fragment (F) with K-feldspar (K) and a rounded polycrystalline quartz grain (Q) (#111618, 484.3 m - GSC #4072-84). **f**) Detrital chamosite (C) (#050120, 436 m - GSC #3680-30).

Plate 2

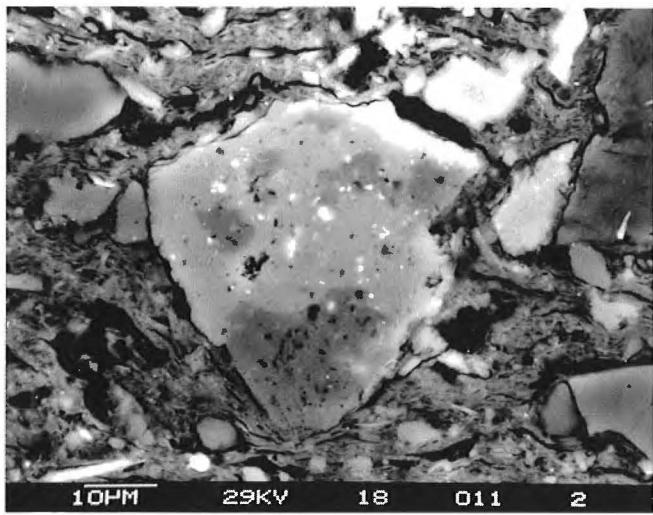

Westgate Formation. **a)** quartz (Q) and pyroclastic plagioclase (P) (#111618, 484.3 m - GSC #4072-80). **b)** volcanic rock fragment with K-rich (light grey) and K-poor (dark grey) zones (#111618, 484.3 m - GSC #4072-82). **c)** zoned volcanic rock fragment with K-rich (light grey) and K-depleted (dark grey) zones. Bright rim is due to edge effects (#111614, 489.9 m - GSC #4072-62). **d)** sand-sized microcline (M) and K-feldspar (K). Note difference in dissolution characteristics. Microcline is pitted and K-feldspar is dissolved at the edge (high magnification of 1D). **e)** silica replaced foraminifera test. This sample is extensively bioturbated. Compare homogeneous matrix fabric with those of 1a and 1b (#111610, 510 m - GSC #4072-60).

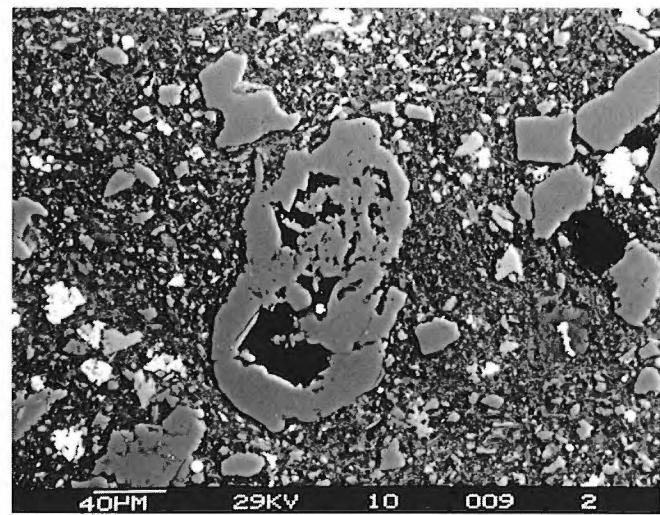

a

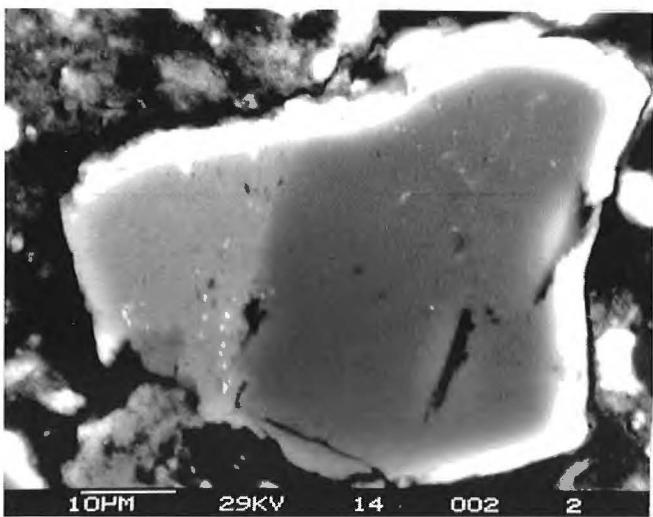

d

e

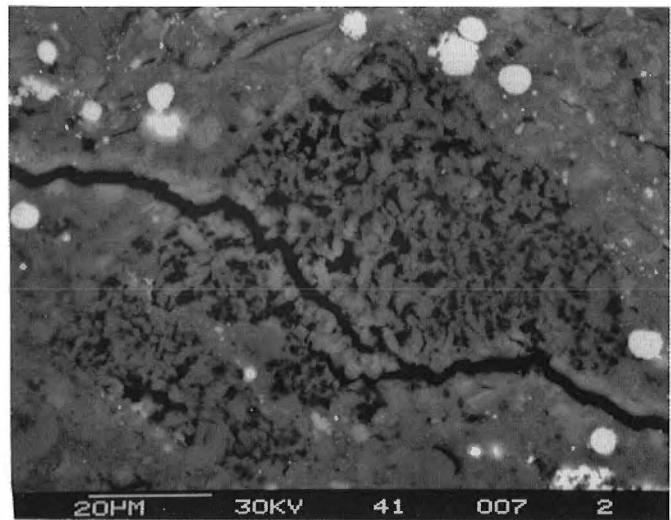

c

Plate 3

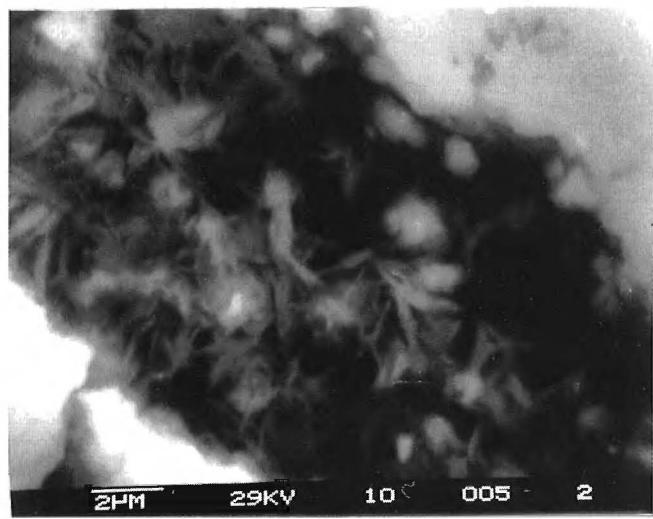

Westgate Formation. **a)** I/S in a quartz "vug" (#111610, 510 m - GSC #4072-57). **b)** high magnification (~10K) of "a". Fibrous habit of I/S indicates an authigenic origin (GSC #4072-56). **c)** authigenic kaolinite shows large vermicular habit (bottom) and a fine-grained pseudomorphic habit (arrows), probably after plagioclase feldspar (#050941A, 1503 m - GSC #3680-115). **d)** kaolinite pseudomorph of a detrital grain, presumably feldspar (#050941A, 1503 m - GSC #3680-113). **e)** kaolinite replacing K-feldspar (arrow) (#050926, 1466 m - GSC #3680-97). **f)** authigenic kaolinite (arrow) replacing a mica(?). Detrital muscovite (M) appears unaltered (#102503, 1327 m - GSC #3680-34).

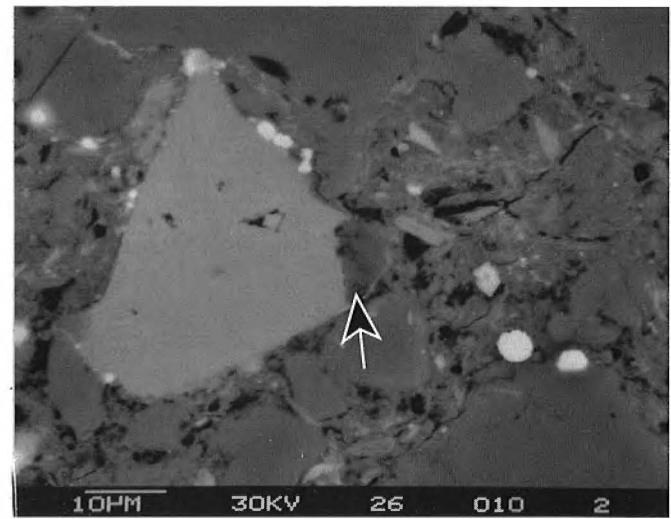

a

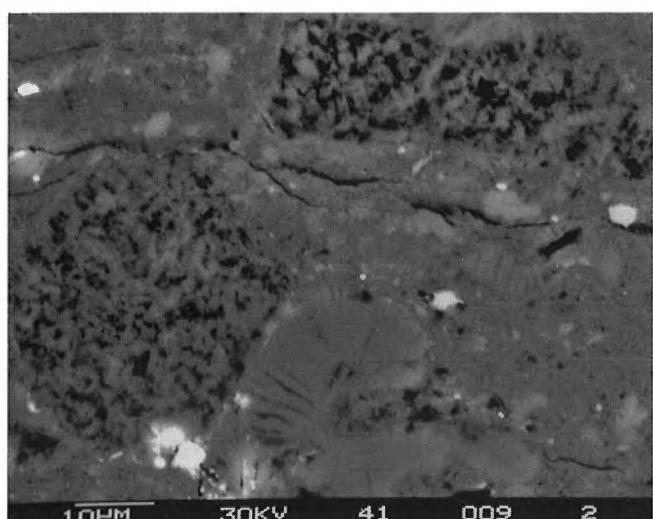

d

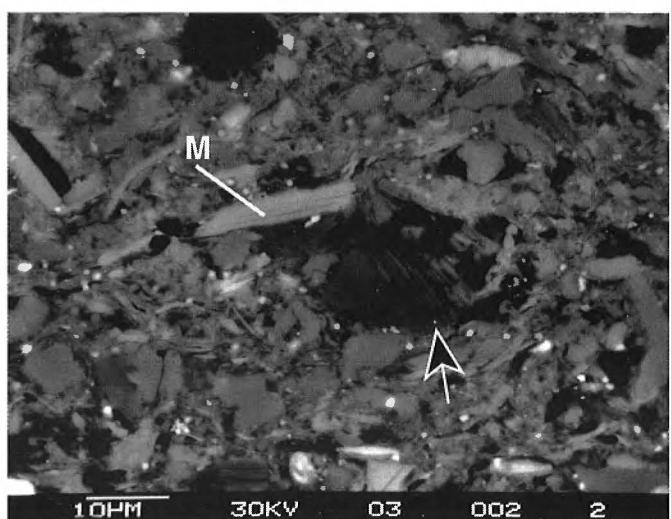

b

e

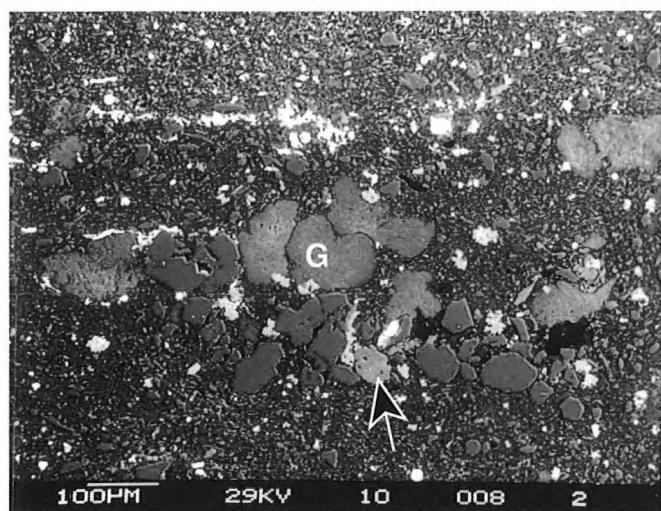

c

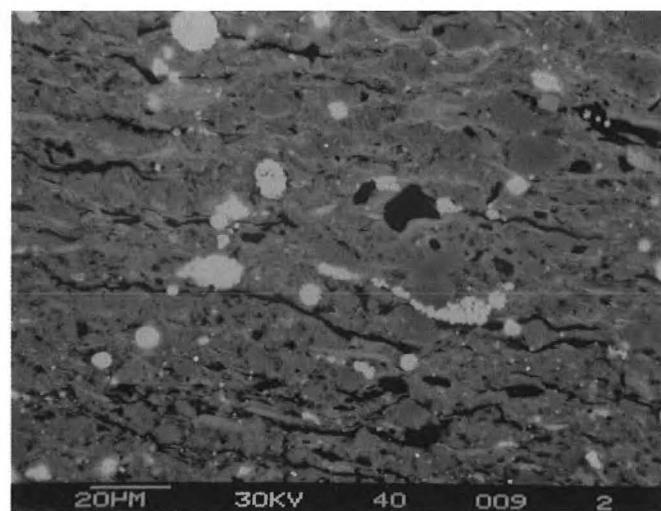

f

Plate 4

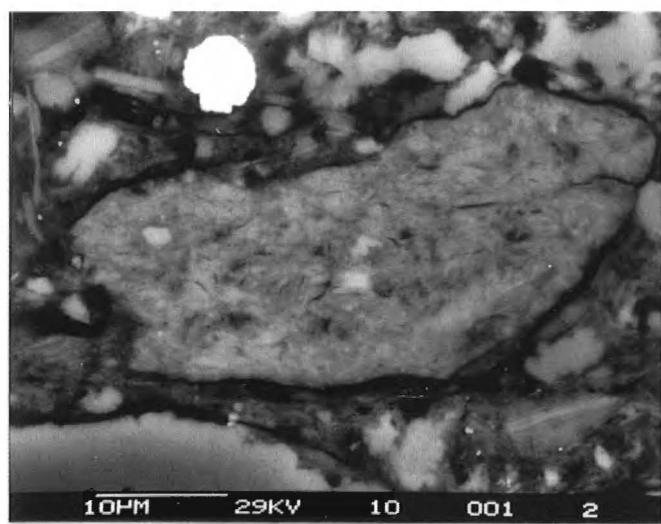

Westgate Formation. **a**) glauconite (G) with quartz (dark grey) grains and K-feldspar (arrow) in a bioturbated siltstone (#111610, 510 m - GSC #4072-60). **b**) "glauconite" grain shows an inclusion-rich, fibrous crystal habit (#111610, 510 m - GSC #4072-52). **c**) bone fragment composed of collophane (dark grey) and crystalline apatite (white inclusions) (#100501, 2566 m - GSC #3680-37). **d**) siltstone matrix with pyrite framboids (white spheres). Matrix shows extensive dissolution and is Fe-rich in top half (#050940, 1496 m - GSC #3680-101). **e**) extensive framework dissolution has occurred in bright zone where the matrix is Fe-rich (#050940, 1496 m - GSC #3680-103). **f**) sutured quartz grains in a zone of intensive dissolution (#050940, 1496 m - GSC #3680-98).

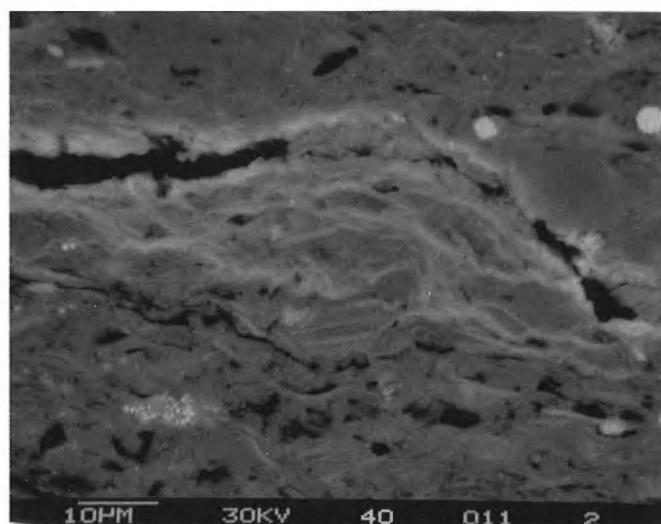

a

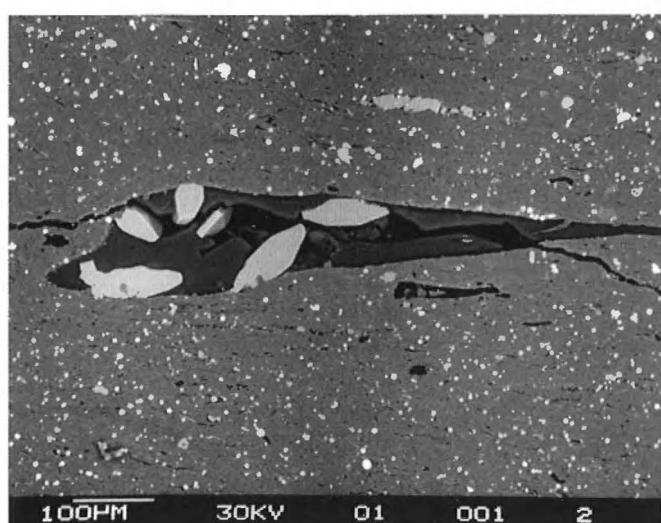

d

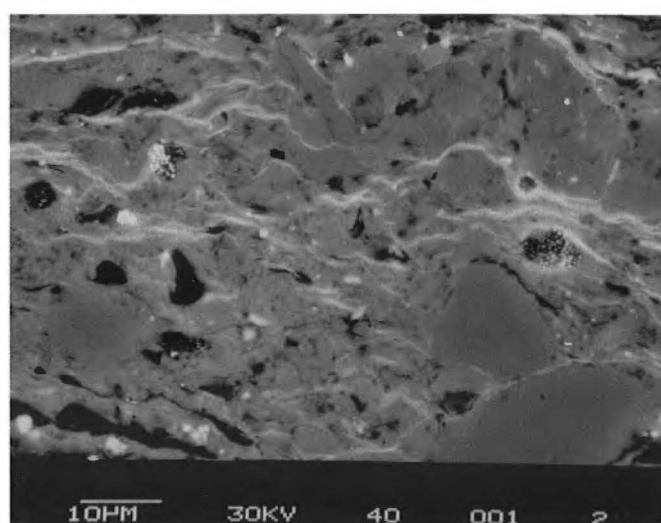

b

e

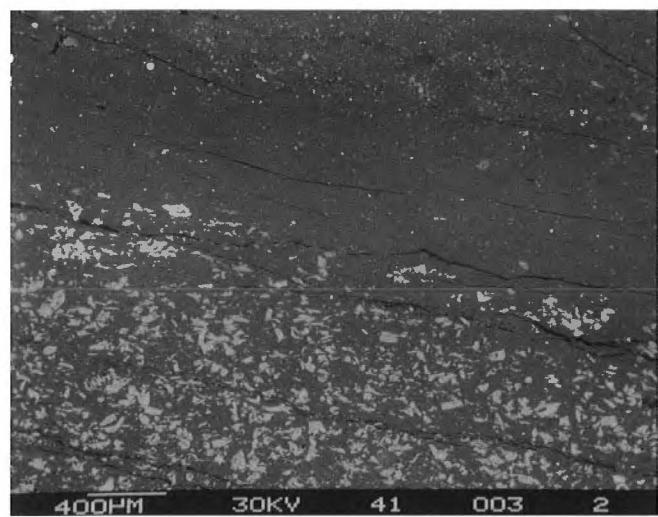

c

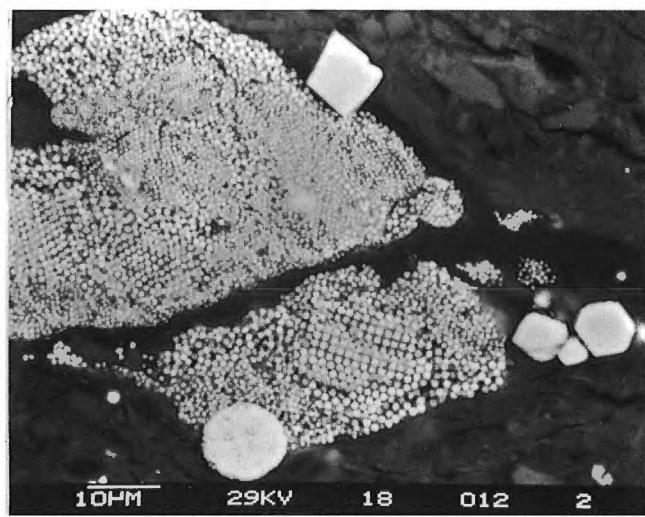

f

Plate 5

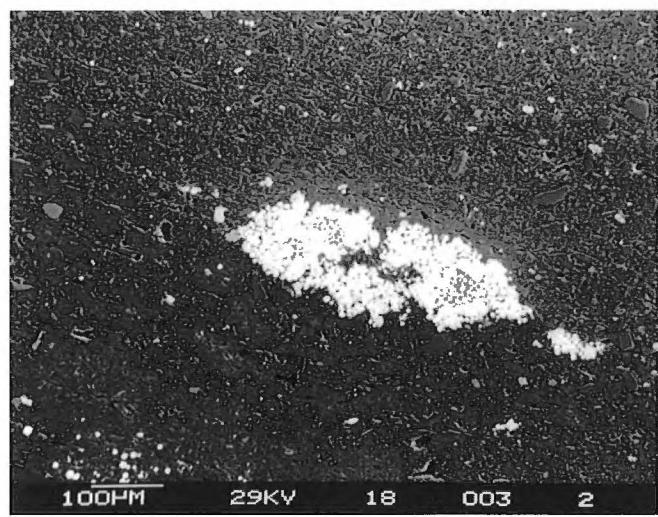

Westgate Formation. **a)** heterogeneous pyrite distribution in claystone. Abundant pyrite in bottom replaces fish debris. Less abundant pyrite in top is dominantly frambooidal (#050941A, 1503 m - GSC #3680-108). **b)** pyrite aggregate in siltstone (#111618, 476.4 m - GSC #4072-74). **c)** reduced contrast, high magnification of aggregate in "b" showing pyrite pseudomorphs of feldspars (F) and "exploded" micas (M) as well as frambooidal and octahedral pyrite (#111618, 476.4 m - GSC #4072-74). **d)** frambooid aggregate showing random, cubic, and closest-packing arrangements (#111618, 476.4 m - GSC #4072-83). **e)** partial pyrite replacement of a bone fragment (#111618, 476.4 m - GSC #4072-72). **f)** partly dissolved detrital TiO_2 grain, probabaly rutile (#111614, 489.9 m - GSC #4072-70).

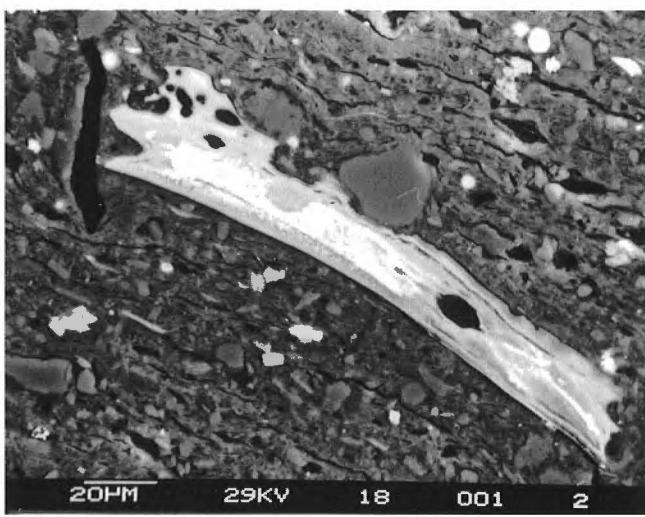

a

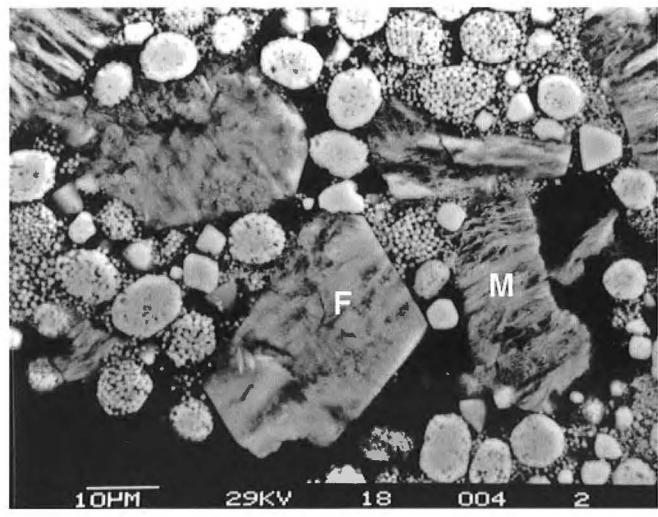

d

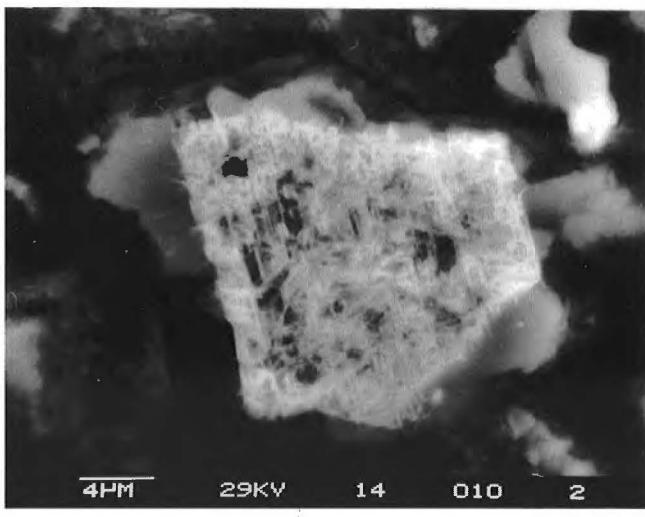

b

e

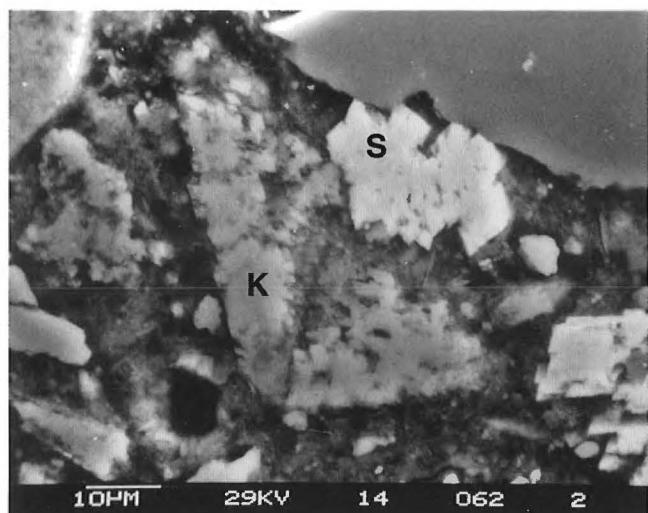

c

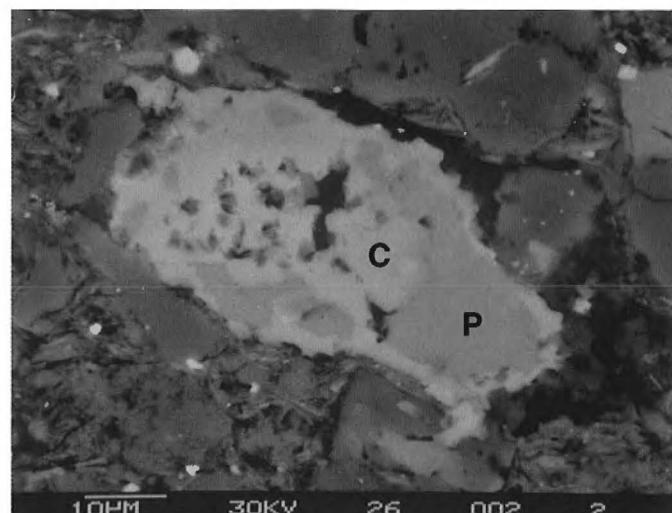

f

Plate 6

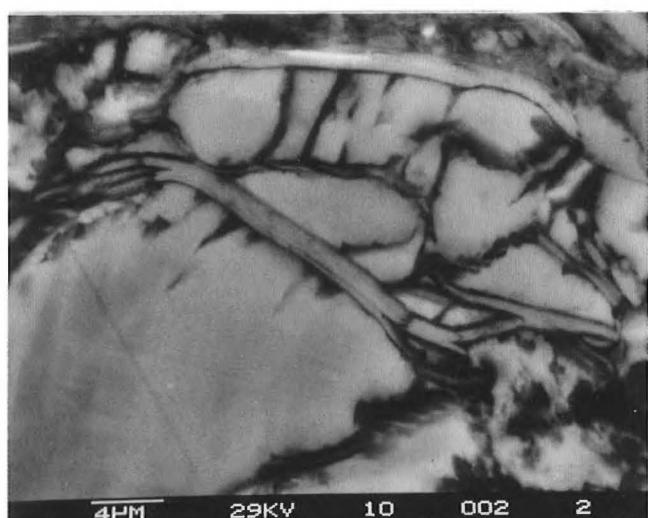

Westgate Formation. **a**) authigenic siderite (S) and partly dissolved K-feldspar (K) in bioturbated matrix (#111614, 489.9 m - GSC #4072-66). **b**) authigenic siderite between laths of muscovite (#111610, 510 m - GSC #4072-53). **c**) Fe-rich carbonate rimming a detrital carbonate bioclast (#102503, 1327 m - GSC #3680-33). **d**) Calcite (C) replacing plagioclase (P) (#050926, 1466 m - GSC #3680-89). **e**) Siderite replaces the cell wall structure and pyrite fills the cells of these algal bodies (#102523, 483 m - GSC #3680-15). **f**) siderite microconcretion, probably replacing a burrow structure (#102503, 1327 m - GSC #3680-85).

b

e

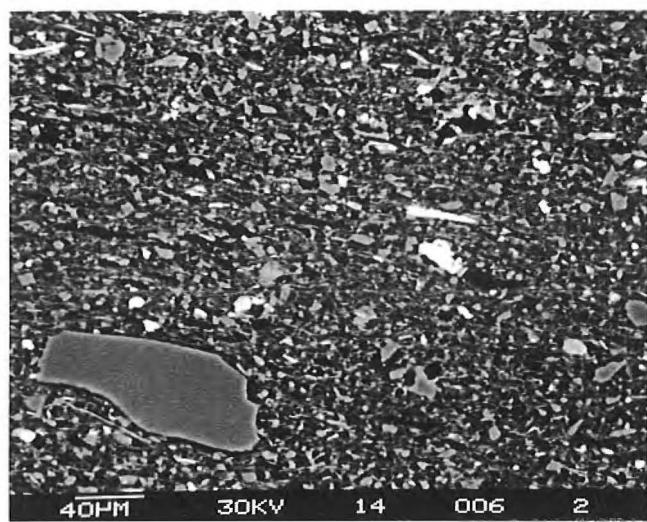

c

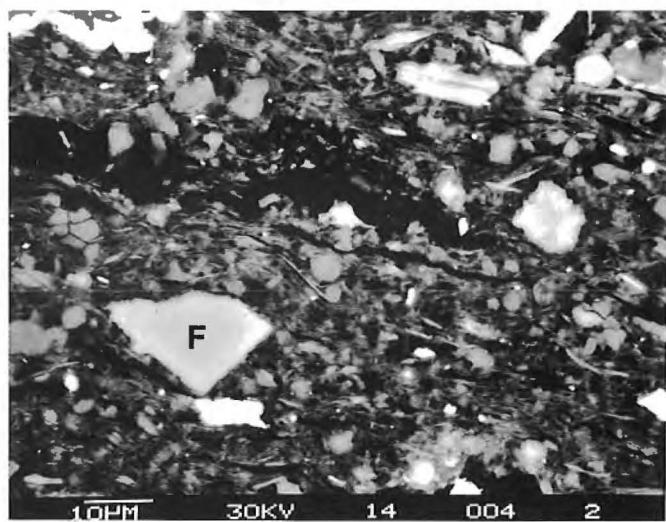

f

Plate 7

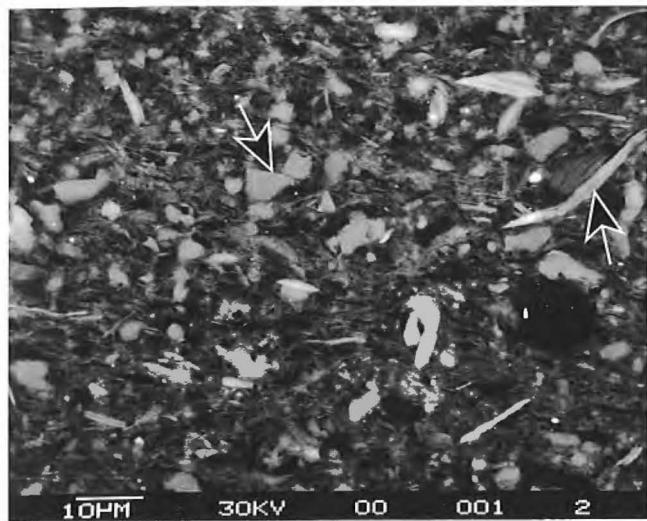

Fish Scales Formation. **a**) sand-sized quartz grain in an otherwise very fine-grained matrix (#103514, 443 m - GSC # 3671-21). **b**) matrix-supported, very fine silt-sized detrital grains of quartz and micas (arrows) (#103514, 443 m - GSC #3671-22). **c**) Ca-rich plagioclase (P) and authigenic, Mn-bearing siderite (arrow) (#103514, 443 m - GSC #3671-18). **d**) well-preserved K-feldspar (F) (#103514, 443 m - GSC #3671-19). **e**) fish bone fragments (lenticular light grey) lie on both sides of a fracture that is partially filled with Ca-sulphate (arrow) (#103514B, 444 m - GSC #3671-29). **f**) higher magnification of bone fragments in fine-grained matrix (#103514B, 444 m - GSC #3671-28).

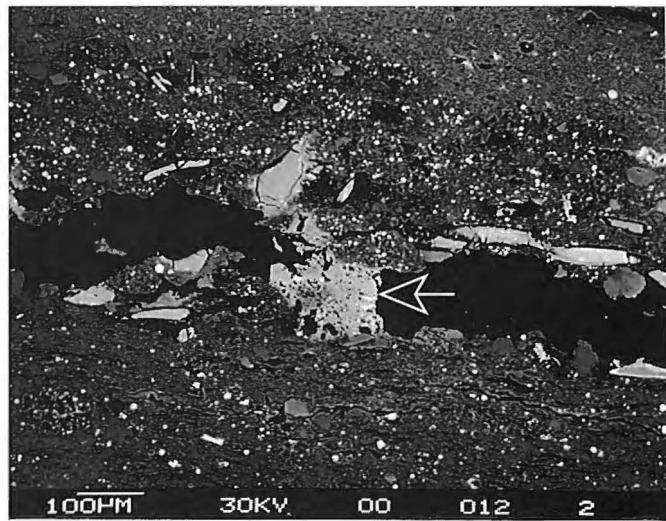

a

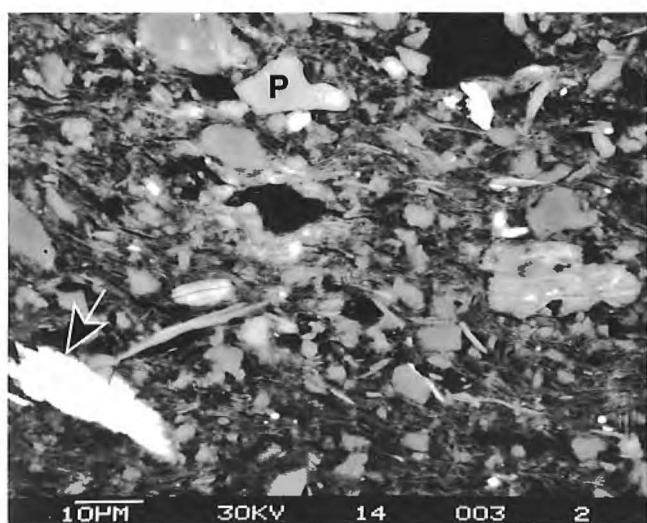

d

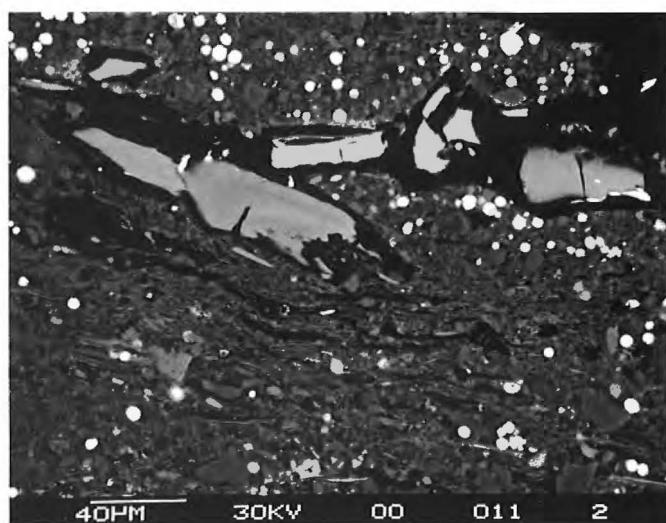

b

e

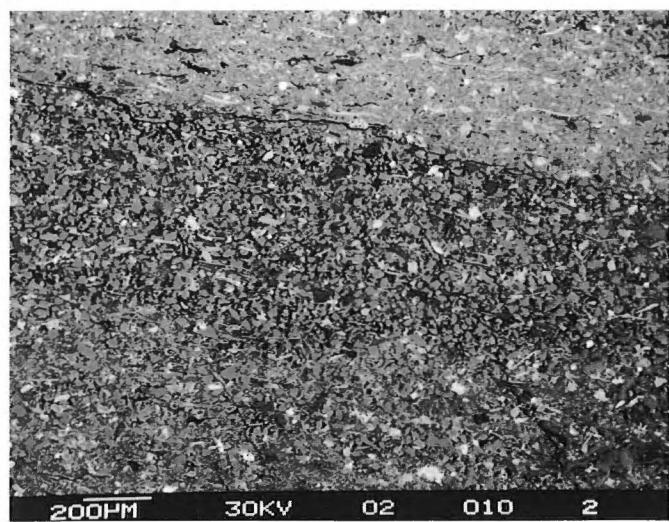

c

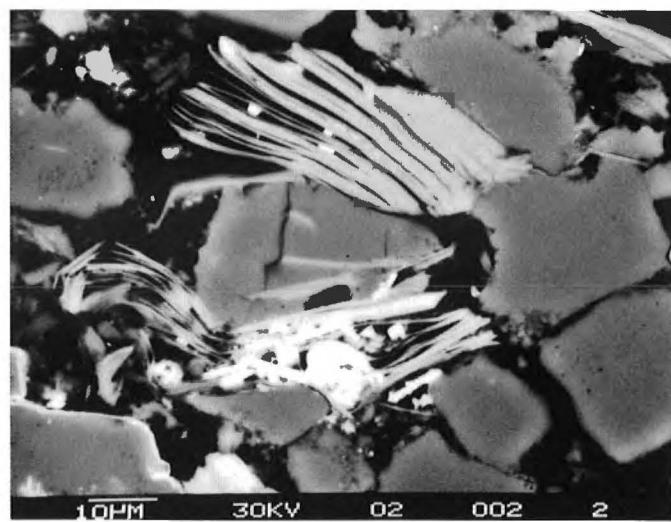

f

Plate 8

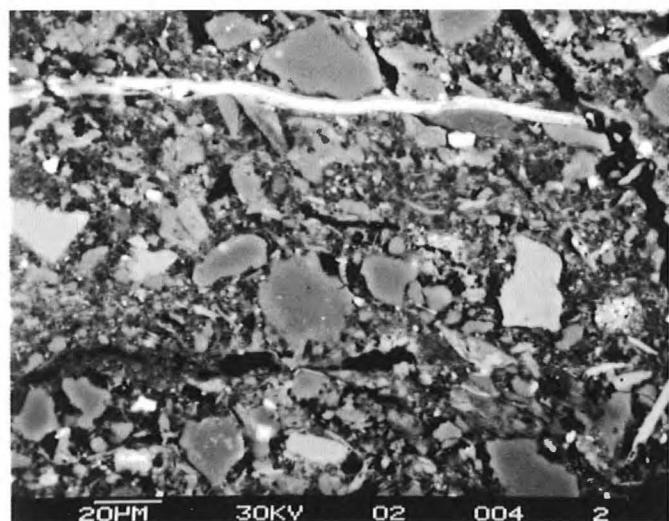

Belle Fourche Formation. **a)** laminated mudstone (top and bottom) and siltstone (middle). Matrix in siltstone appears black because it has been plucked during polishing. Plucking of matrix in framework-supported material is common (#050102, 384 m - GSC #3860-26). **b)** mudstone matrix showing a large, detrital muscovite (top), K-feldspars (light grey, left and right) and quartz (#050102, 384 m - GSC #3860-20). **c)** foraminifer and small ostracod (?) tests filled with authigenic kaolinite. White spheres are frambooidal pyrite (#090907, 32268 m - GSC #3860-75). **d)** compactionally deformed muscovite (top) and biotite (bottom) with quartz grains and intergrown siderite. Note quartz suturing in contact with muscovite (#050102, 384 m - GSC #3860-18). **e)** detrital chamosite (bottom) with muscovite (left) and an "exploded" biotite (top) with intergrown siderite (#050102, 384 m - GSC #3860-22). **f)** sideritized fecal pellet (#050102, 384 m - GSC #3860-17).

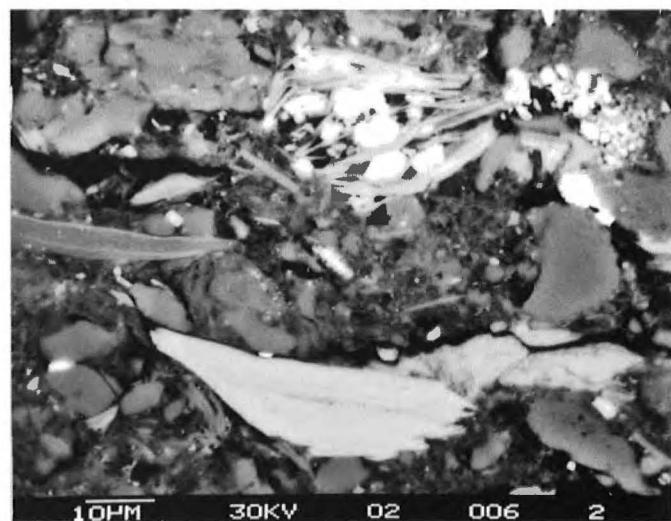

a

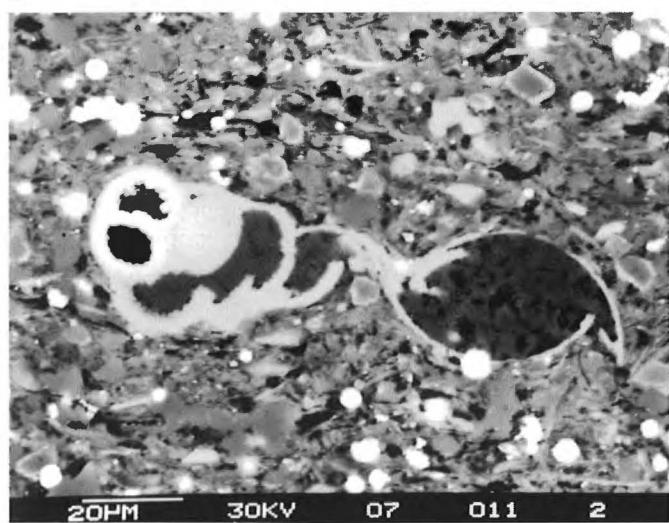

d

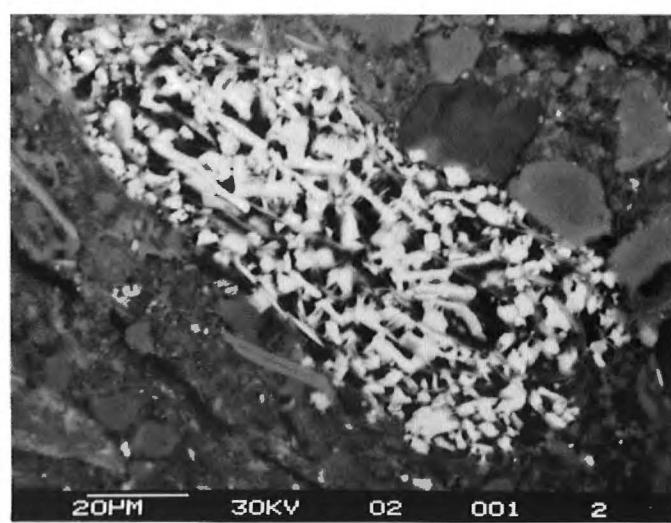

b

e

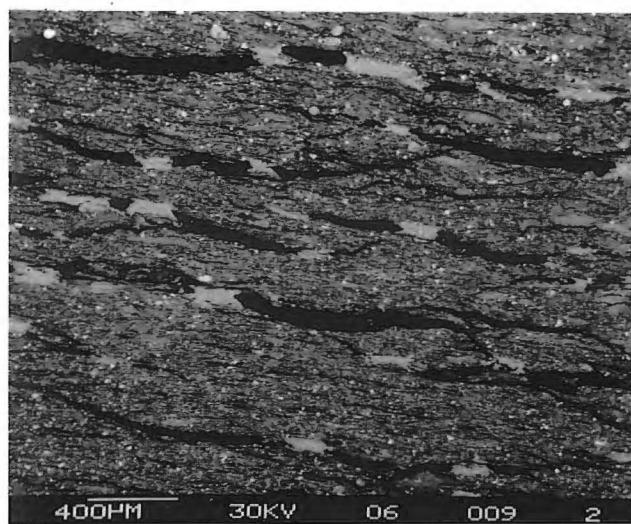

c

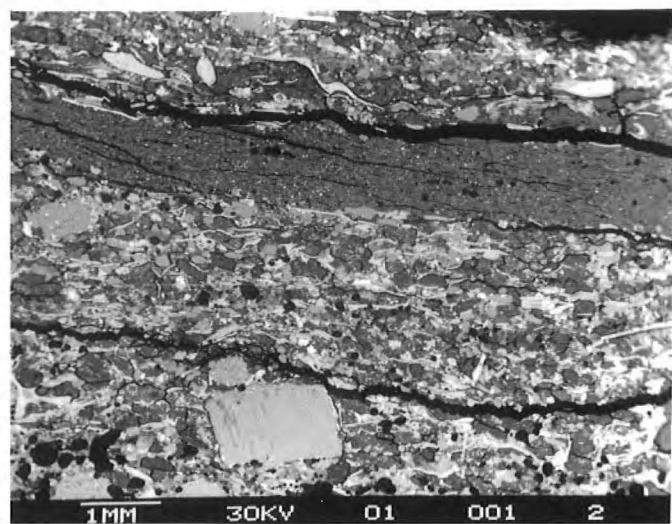

f

Plate 9

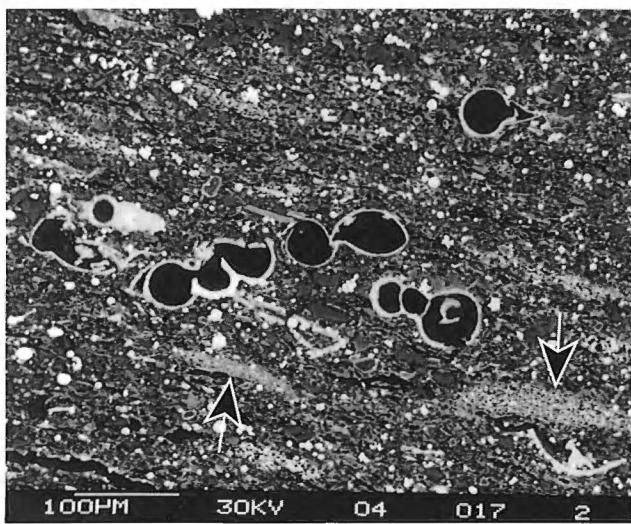

Second White Specks Formation. **a)** bedding-parallel fractures partly filled with Ca-sulphate (light grey), probably gypsum. Note homogeneous distribution of pyrite framboids (white spheres) (#0103506, 413 m - GSC #3671-12). **b)** flattened fecal pellets (arrows) are the "specks" in the Second White Specks Formation. Kaolinite-filled foram tests are abundant as is framboidal pyrite (#041304, 2114 m - GSC #3671-53). **c)** secondary-electron image of coccoliths and rhabdoliths (laths) that make up the fecal pellets shown in "b" (#063410, 738 m - GSC #3897-51). **d)** laminated bioclastic hash (top and bottom) with claystone. Inoceramid prism fragment is at lower left (#061801, 398 m - GSC #3680-57). **e)** Bioclasts include a fish vertebra and Inoceramid prisms (arrows). Dark areas are I/S-rich matrix. Calcite cement fills spinal cord cavity and below vertebra (#061801, 398 m - GSC #3680-64). **f)** high magnification of siliciclastic matrix shows fine silt-sized quartz with muscovite (upper right) and K-feldspar (arrow) in clay matrix (#103402, 408 m - GSC #3680-82).

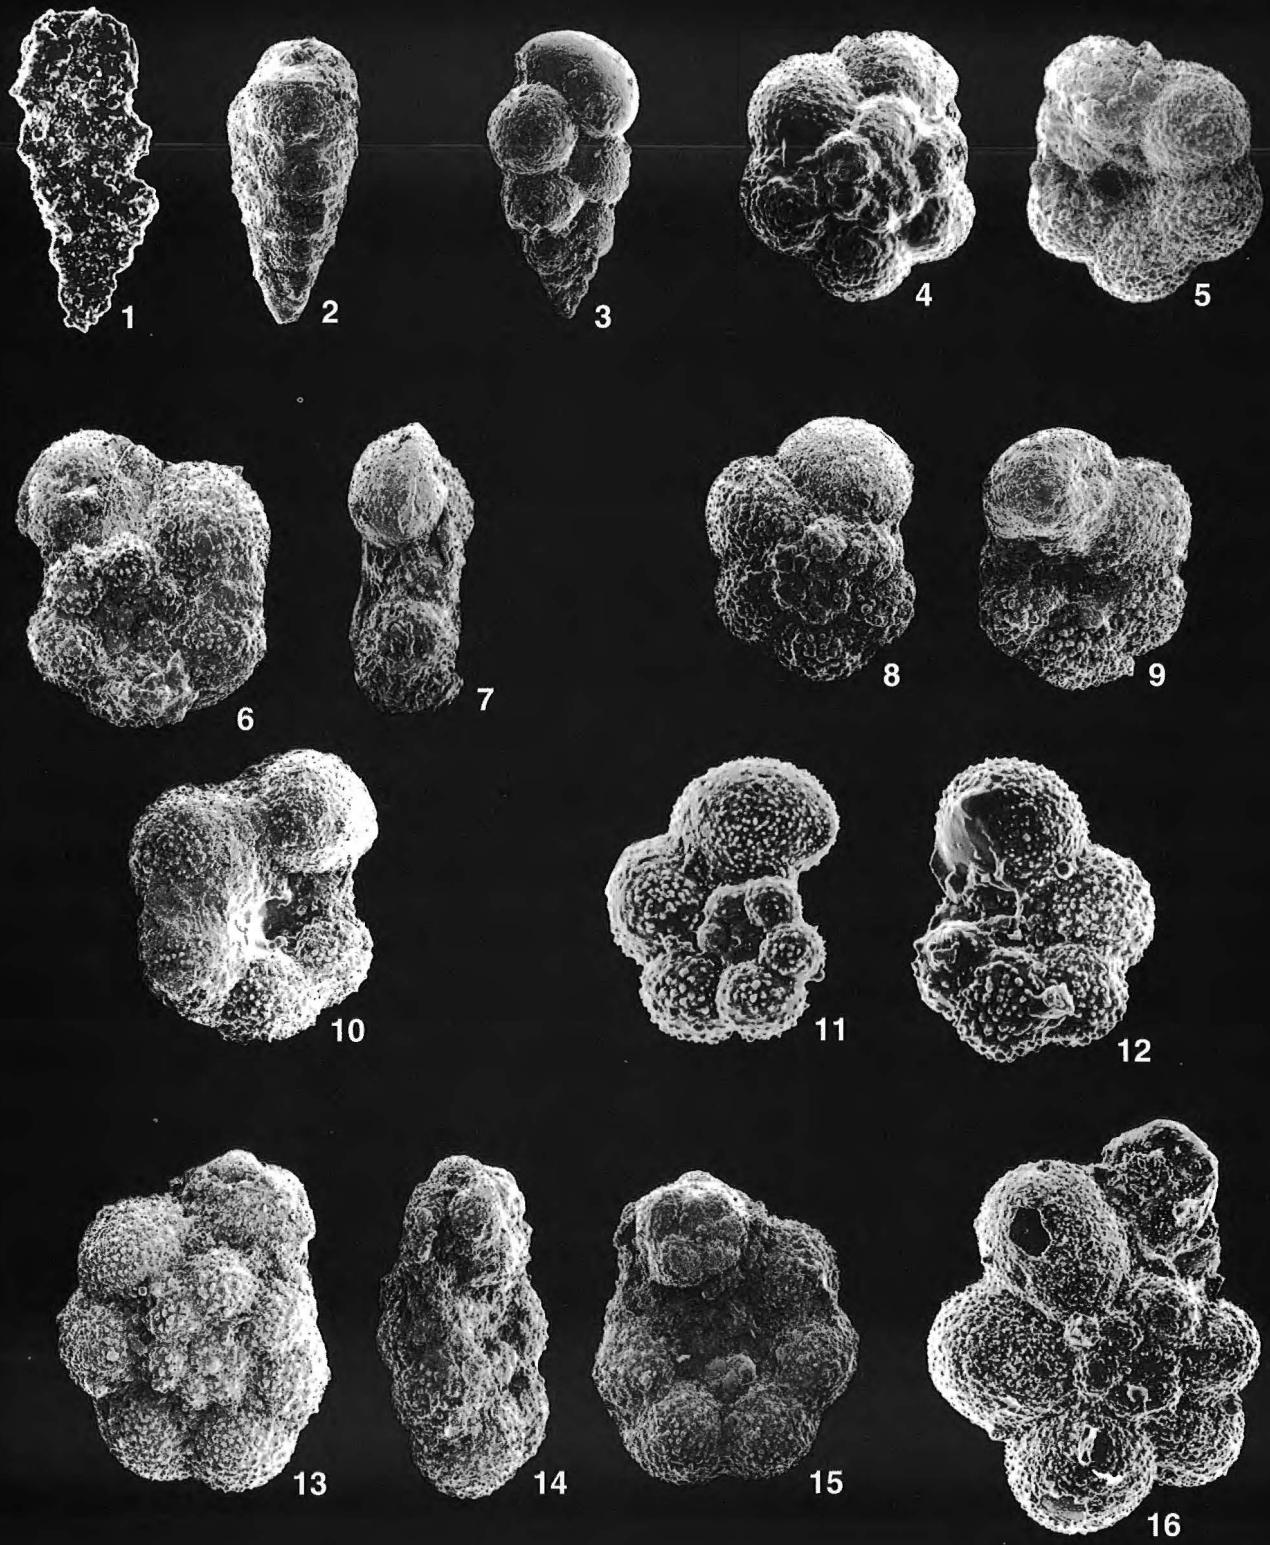

Plate 13

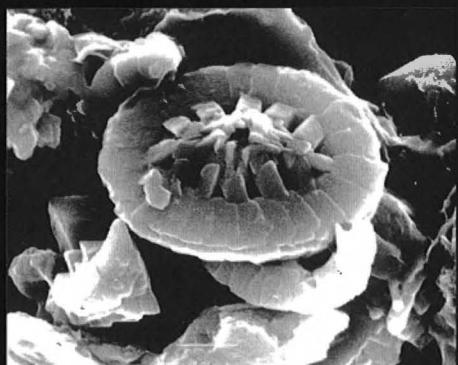

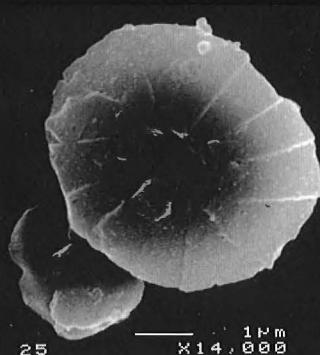

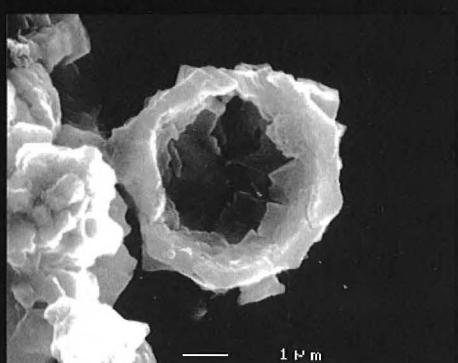

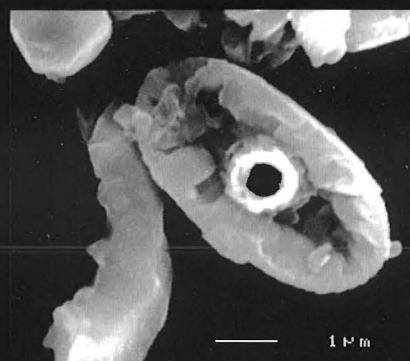

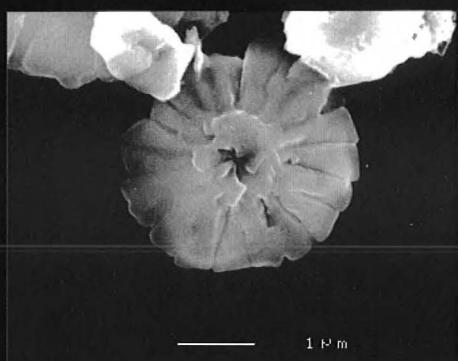

Plate 14

Bioturbated (3A and 6A) and laminated concretions (4, 5A and 2A). 6A and 5A are rimmed with pyrite. 4 shows remnant bedding crosscut by calcite-spar-filled septa. These concretions show no isotopic zoning (see Table 7).

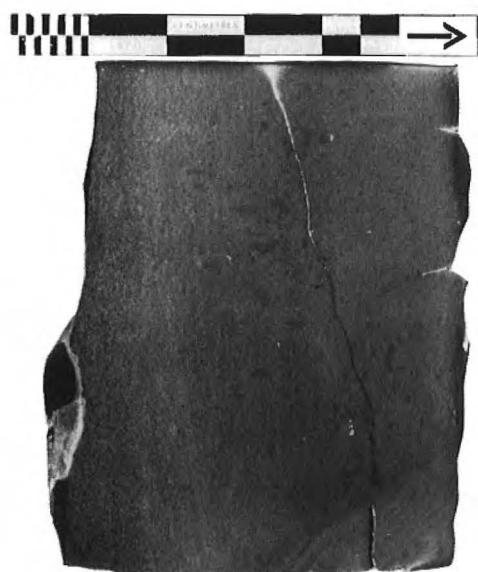

9-9-56-19W5 #6A

CG91-4

16-1-61-22W5 #3A

10-34-42-22W4 #5A

10-34-42-22W4 #2A

Plate 15

Isotopically zoned siderite concretion 2B from the Westgate Formation (10-25-65-20W5, 1325 m). This concretion also shows evidence of bioturbation, as in sample on Plate 16, but contains botryoidal pyrite throughout. Botryoidal pyrite fills uncompacted burrows indicating early cementation. Textural zoning is not evident.

10-25-65-20W5 #2B

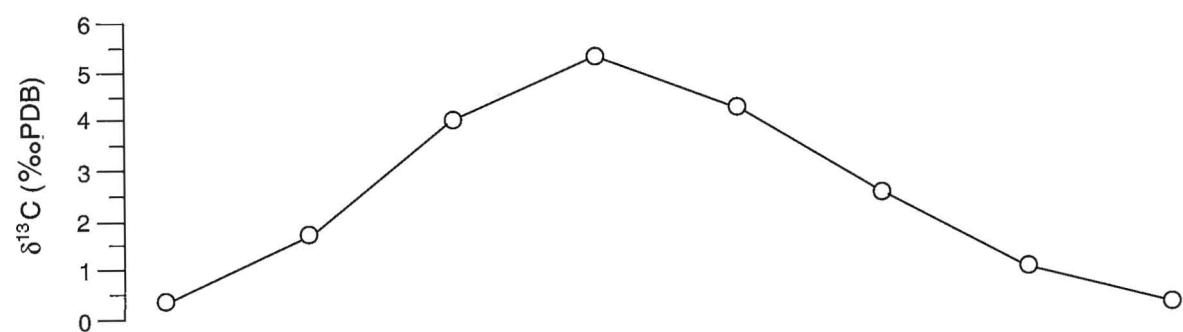

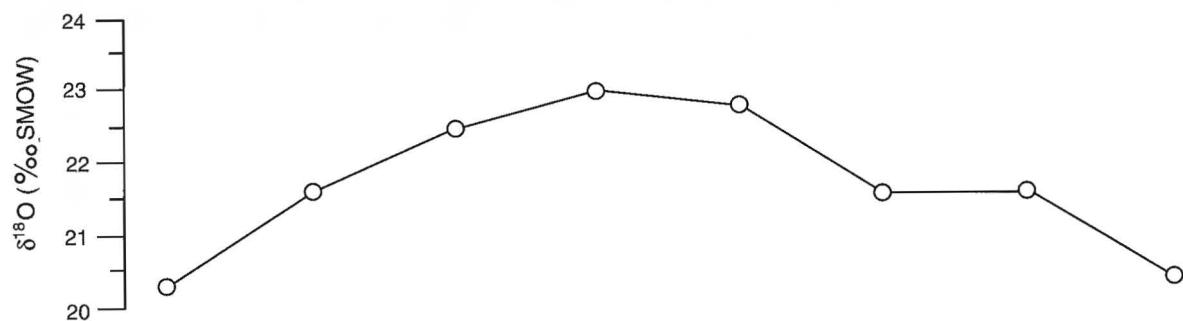

Plate 16

Texturally and isotopically zoned siderite concretion 2A from the Westgate Formation (10-25-65-20W5, 1324.7 m). Center of concretion is well-bioturbated and margins contain abundant, botryoidal pyrite. Light grey, wispy, star-shaped areas are dolomite. Partly flattened large burrow (~1.5 cm wide) is visible just below center of the concretion.

10-25-65-20W5 #2A

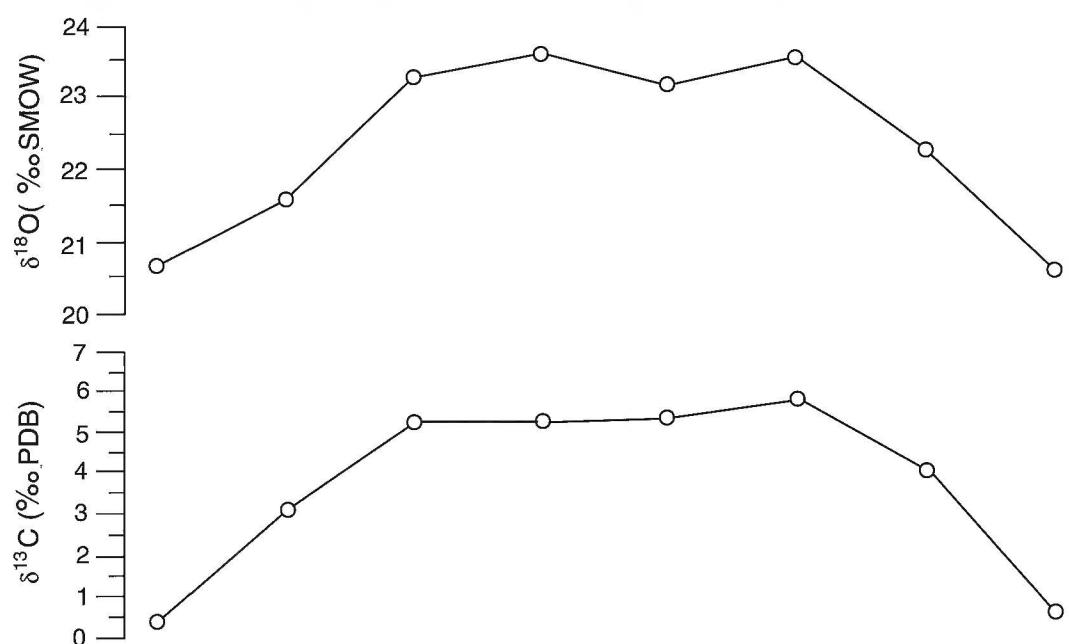

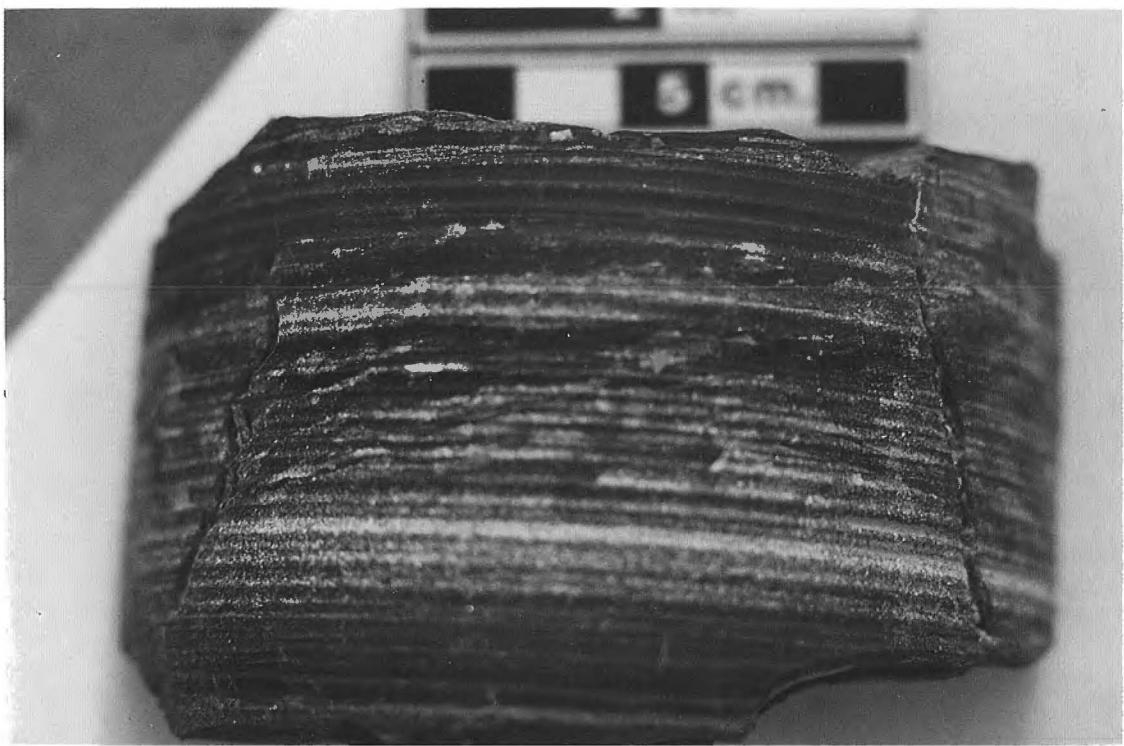

Plate 17

a) coring-induced petal-centerline fractures (terminology after Kulander et al., 1990) in the Second White Specks Formation. b) induced fracture surface showing slickensides (arrow), Second White Specks Formation.

a

b

Plate 18

a) parallel fracture sets in the Jumping Pound Sandstone, which directly overlies the Second White Specks Formation, Highwood River outcrop (see Table 1 for location). **b)** close-up of **a** shows clearly that bedding-perpendicular fractures are filled with calcite. Hammer (33 cm in length) is oriented parallel to direction of thrusting.

a

b

Plate 19

a) calcite-filled, bedding-perpendicular fractures (below notebook) and bedding-parallel fractures (above notebook). Note difference in fracture set spacing. Notebook is 21 cm in length. Highwood River outcrop (see Table 1 for location). **b)** oil stains (arrow) on fresh fracture surface. Highwood River outcrop.

a

b

Plate 20

a) bedding-perpendicular calcite-filled fractures in the Second White Specks Formation. Strata at this location are complexly folded and these fractures result from folding-induced extension. Mill Creek Bridge outcrop (see Table 1 for location). **b)** close-up of fracture fill cement in **a**. Thin laminae give way to coarse spar suggesting successive cementation events in response to increased fracture volume. Note small Inoceramid impression (arrow).

Plate 21

a) fractured sandstone bed indicating brittle behaviour whereas mudstone reflects ductile deformation. **b)** fracture porosity is preserved in ductile mudstone. **c)** well-preserved fracture porosity. **d)** annealed fracture porosity. Note slickensides on dark core face. All samples from Dome et al Claresholm well (14-29-11-28W4; 2502-2521 m depth).
