GEOLOGICAL SURVEY OF CANADA | COMMISSION GÉOLOGIQUE DU CANADA

DESCRIPTIVE NOTES

INTRODUCTION

This bedrock geological map summarizes the initial results of mapping by the Geological Survey of Canada (GSC) and the Canada-Nunavut Geoscience Office (CNGO) in the Flint Lake area of central Baffin Island (See also GSC OF 4004, CNGO OF 2000-001). The area is underlain by Archean gneiss, granite, and supracrustal rocks, Paleoproterozoic plutonic and supracrustal units mapped during the first summer of the three-year (2000-2002) partnered field project are presented in Corrigan et al. (2001). Field work in 2000 yielded a transect across the project area from 68° to 70° N (approximately 250 kilometres in length) and extending 45 to 100 kilometres inland from the northeastern shore of Foxe Basin. From north to south, the transect provides a continuous section across the southeastern margin of the Archean Nadluardlak Lake and the Paleoproterozoic Piling Group and the northern margin of the ca. 1.80–1.84 Ga Cumberland batholith.

The first systematic mapping of the area was undertaken at reconnaissance level between 1965 and 1970 (Jackson 1969, 1978, 1984, 2000; Jackson and Taylor, 1972), and in 1974 and 1975 (Morgan et al., 1975, 1976; Jackson and Morgan, 1978; Morgan, 1983). More detailed work was subsequently initiated in the southeastern Cumberland batholith (Jackson and Berman, 1993; Scott, 1997, 1999; Scott et al., 1997), and in the Foxe Fold Belt (Jackson et al., 1988, 1989; Henderson and Henderson, 1994). The most recent work in proximity to the current project area consists of bedrock mapping and U-Pb geochronology of Archean rocks in the Eqe Bay area (Bethune and Scammell, 1997), and a lake-sediment and water-regional geochemical survey southwest of the Barnes Ice Cap (Cameron 1996; Friske et al. 1998).

The new work presented below is based on systematic bedrock traverses with approximately two to three kilometres spacing.

GEOLOGICAL SETTING

The project area straddles the northern margin of the Trans-Hudson Orogen on Baffin Island (Lewry and Collerson, 1990; Reid Fold Belt). The orogenic margin separates west-vergic Archean rocks of the Rae Province from the east-vergic Archean rocks of the Hearne Province and to the south by the Cumberland batholith. The main lithological assemblage consists of the Piling Group, which comprises a thin lower sequence of mantle, quartzite, schists, and minor iron-formation of probable shelf origin, and a thick upper sequence of turbidites and basalt. The Piling Group has been variously interpreted as foredeep flysch (Morgan et al., 1975; Henderson et al., 1988; Jackson, 2000), Mafic volcanic rocks have been recognized within the Piling Group (Bravo Lake Formation) and historically interpreted as mafic and ultramafic flows and sills intercalated with the lower sequence of the Piling Group (Tippett, 1980; Henderson et al., 1988; Henderson and Henderson, 1994). Archean basement is interpreted to occur north of the Piling Group as well as within the Nadluardlak Lake area and as a series of inliers within the Cumberland batholith (Jackson, 2000; Henderson 1994). New observations outlined below suggest, however, that at least a proportion of what had been initially interpreted as Archean basement in the Flint Lake and MacDonald River area may in fact include Proterozoic intrusions. The following sections outline the results of new geological mapping in 2000, described sequentially from north to south, or from lowermost to highest exposed structural levels.

TECTONOSTRATIGRAPHIC UNITS

Archean basement rocks (units Agn-Agp)

Archean rocks have previously been interpreted to underlie most of the area north of the Piling Group and to form basement inliers within the Piling Group (Fig. 1; Jackson, 2000; Henderson et al., 1988). Our new mapping and observations in the vicinity of the Archean basement/Paleoproterozoic cover contact suggest that the latter is encountered by a number of syn- to postectonic felsic plutons of likely Proterozoic age, especially in the area around Flint Lake. Consequently, areas underlain predominantly by Archean rocks seem to be restricted to a more northern part of the project area, where they comprise biotite ± hornblende quartzofeldspathic orthogneisses of granodioritic to monzogranitic composition (unit AgnI), and hornblende-biotite ± clinopyroxene amphibolite (unit Agn). As well as minor hornblendebiotite ± clinopyroxene amphibolite (unit Amb). These rocks extend along strike to the southwest in the Eqe Bay area, where they have yielded U-Pb zircon ages ranging between 2.84 – 2.71 Ga (Bethune and Scammell, 1997). The orthogneisses and supracrustal rocks are pervasively intruded by massive to strongly foliated plutonic rocks of predominantly biotite monzogranite composition (unit Agr), and by distinct bodies of biotite ± hornblende quartzofeldspathic orthogneiss of granodioritic to tonalitic composition (unit Agt). Hornblende ± clinopyroxene gabbro (unit Agb) intrusive the biotite monzogranite (unit Agr) in northeast and southeast of Lake Gillian. Similar plutonic rocks and dykes in the Eqe Bay area yield Archean ages (ibid.).

Northern Paleoproterozoic plutonic rocks (unit Pgr)

In the Flint Lake area, as well as in the area of the MacDonald River, the distribution of Archean basement is complicated by the presence of biotite-allanite ± hornblende monzogranite (unit Pgr) that is clearly intrusive into Archean basement rocks and Piling Group supracrustal rocks. Contacts are commonly sharp and discordant, and xenoliths of mantle, psammite, quartzofeldspathic orthogneiss (unit Agn) and hornblende-clinopyroxene-biotite quartz diorite. Commonly the granite sits structurally above the Piling Group it intrudes. In contrast, plutonic rocks in concordant structural contact with the Paleoproterozoic supracrustal units are often foliated, completely recrystallized, and/or layered and interpreted as part of the Archean basement (i.e. units Agn and Agr described above). Pgr is also distinguished from Archean basement rocks by its lack of penetrative fabrics, although this doesn't always apply, making the distinction between reworked Proterozoic intrusions and Archean basement less straightforward in some areas. Total field aeromagnetic maps of the Flint Lake area (W. Miles, GSC; unpublished data) seem to indicate a rough correlation between areas of potential Archean basement and regions of high magnetic anomalies (see also Jackson, 2000, p. 231). This may provide a useful tool to place additional constraints on the extent of Archean basement rocks in areas of poor outcrop. Unfortunately, Pgr is difficult to map using aeromagnetic geochemistry, as well as reconnaissance gamma ray spectrometric measurements (K, Ford, GSC) were undertaken in order to further define areas underlain by basement versus Proterozoic plutonic rocks in the northern portion of the project area.

A unique muscovite feature observed in the northern portion of the project area, especially around Flint Lake, is a distinct increase in the abundance of muscovite in Pgr. Locally, muscovite is found in pegmatites and granitic pegmatite, which occurs in abundance in aureoles surrounding the plutons. These aureoles are a few kilometres thick and consist of numerous, discontinuous pegmatite sills injected in the Piling Group metasedimentary rocks. The pegmatites, as well as the metasedimentary rocks, are structurally concordant with the pluton outlines and suggest the presence of abundant fluids in the immediate metasedimentary wallrock during pluton emplacement. Similar pegmatites are also found in the Archean basement rocks in the Eqe Bay area. The pegmatites have been interpreted as the potential product of shear heating at the interface between Archean basement and Proterozoic cover (G. Jackson; pers.com.).

The presence of potential Archean inliers in antiformal culminations in the Dewar Lakes area (east of the area covered by the present map; NTS 27 B) had been known since the early reconnaissance work of Jackson (1969), Morgan et al. (1975) and Morgan (1983). Jackson (1969) described the Archean rocks as "...a heterogeneous migmatitic orthogneiss and banded gneiss of predominantly tonalitic composition that are separated from the Lunguet Bluff Formation by a narrow (few tens of metres) unit of banded quartzite, metachert, silicate-facies iron formation and amphibolite, interpreted as Dewar Lakes Formation (see also Henderson et al., 1988).

Piling Group (units PHs-PPd)

The Piling Group is continuously exposed from the Flint Lake area to approximately the southern limit of the project area (68° N), as well as in narrow bands between MacDonald River and Flint Lake. In the Flint Lake area, a lower sequence consists of muscovite schist and quartzite intercalated with minor iron-formation (Dewar Lakes Formation; PHs), and an upper sequence consists of a basal assemblage of mafic pillow lava and pillow breccia (Bravo Lake Formation; unit PHv). An upper sequence consists of a basal assemblage of black pelite, ferruginous psammites, and sulfide-facies iron-formation (Astarte River Formation; unit PHi) that is overlain by a thick assemblage (few kilometres?) of thin- to thick-bedded psammite, feldspathic wacke, with thin intercalations of semipelite and pelite, and local cab-rolcalcsie beds and pods after carbonate concretions (Longstaff Bluff Formation; unit PHLb). Locally, the psammites contain abundant, 1 to 2 millimetre, rounded blue quartz grains and, more rarely, 1 to 2 centimetre sized feldspar crystals and rounded blue quartz, as well as finegrained, angular, lithic fragments of supracrustal origin. The association of equidimensional authental feldspathic grains and rounded blue quartz suggests derivation, at least in part, from felsic volcanic rocks (Corrigan et al., 2001).

Rocks from the lower sequence are mostly found in the Flint Lake area. However, a relatively thin apron of mafic pillow lava and pillow breccia (unit PPv) is also found in the northeastern part of the project area, where it overlies metabasite (basement) and iron-formation occurs between the structural culminations cored by potential Archean gneisses (unit Agn) and the psammites of the Longstaff Bluff Formation (units PHLs and PHLp) in the southern portion of the map area. Henderson and Henderson (1994) interpreted a similar association in the Dewar Lakes area (NTS 27 B) as part of the lower sequence.

Rocks from the upper sequence and intrusive rocks and associated sedimentary units occur in an easterwest corridor that extends from Straits Bay to and beyond Western River. In the area investigated this past summer, this package is preserved in a series of isolated klippen structures as a result of F_3-F_4 crossfolding (see below). The largest of these klippen, located southwest of Nadluardlak Lake (unit PPd) is characterized by a lower unit several hundred metres in thickness of mostly of mafic and ultramafic cumulate layers and sills. This unit is overlain by a thick (more than 1 kilometre) succession of mafic pillow lava and pillow breccia (unit PPv). Pillow structures are generally very well preserved, and together with paleovolcanological indicators such as pillow shelves, consistently indicate upward-younging directions. Volcanic flows are locally intercalated either with banded calc-silicate rock and mafic sedimentary units, finely laminated semipelite, or rusty psammite and black pelite. The contact between the volcanic rocks and the underlying sedimentary rock of the upper sequence Piling Group is defined by a subvolcanicmal highestain zone up to 50 metres thick with rare shear-sense indicators suggesting top-the-NNE displacement (i.e. thrust fault; Corrigan et al., 2001). Moreover, a highly heterogeneous, highly sheared rock assemblage resembling a tectonic mélange was identified beneath some of the mafic klippen (H. Hallmandel, pers. com.). This assemblage, measuring up to a few tens of metres in thickness, contains centimetre- to metrescale blocks of mafic, ultramafic, carbonate, granite and silicoclastic sedimentary rock in a matrix of metamorphosed mafic volcanic rocks. The origin of this unit is interpreted as part of an M.Sc. thesis study on the structural elements of the project area (F. Bernolles; Queen's University).

The volcanic rocks in the Nadluardlak Lake area were correlated with mafic and ultramafic rocks east of the Western River (Dewar Lakes area; NTS 27 B) and named Bravo Lake Formation (unit PHt) by Tippett (1984). In the Dewar Lakes area, amphibolite, hornblendite and ultramafic bodies of the Bravo Lake Formation have been interpreted as a suite of layered mafic intrusions (Jackson, 1969; Morgan et al., 1975; Morgan, 1983; Jackson, 1985) and Henderson and Henderson (1994). Field work in 2001, as well as a trace and major element geochemical study presently in progress, will test the correlation between the volcanic rocks preserved in the set of klippen west and east of Nadluardlak Lake and the intrusive bodies in the Dewar Lakes area (NTS 27 B) and form part of a Ph.D. thesis study on the petrology and petrogenesis of the Bravo Lake Formation by S. Modeland (McGill University).

Southern Paleoproterozoic plutonic rocks (units PCgk-Pggr)

Plutons that occur in the southern portion of the project area are compositionally more diverse and have different relative ages than the Paleoproterozoic plutons described above. Field relationships suggest that plutons which we will in Manitoba (N. Wodicka, pers. com.), and are associated with subfacies metasediments, providing a context possibly similar to that of the Reglet deposit in the Cape Smith Belt. Although Henderson and Henderson (1994) attribute little economic interest to these sills, it should be noted that occurrences of disseminated and massive sulphides were noted in the Bravo Lake Formation during the course of systematic field work in 2000. These with aluminous metasediments. Plutons of the Cumberland batholith contain enclaves of foliated and folded migmatitic metasedimentary rocks of the Longstaff Bluff Formation (unit PHLp), suggesting that the latter was being deformed and metamorphosed prior to and/or during intrusion by the batholith. Plutons of the Cumberland batholith are themselves intruded by white to lightpink, medium-grained to pegmatitic garnetbiotite ± muscovite ± cordierite monzogranite (unit PCgk) and pink, coarse- to very coarse-grained, locally pegmatitic monzogranite (unit Pggr). This reaction eventually leads to production of large quantities of melt (unit PCgk) and we would suggest that, with the production of garnet ± cordierite bearing granitic plutons (unit Pggr). The spatial relationship between the Cumberland batholith and the highest metamorphic grades observed in the Longstaff Bluff Formation (unit PHLp), together with the emplacement of the garnet ± cordierite bearingunites (unit Pggr), suggests that heat input by intrusion of the batholith was responsible for the metamorphism of the Longstaff Bluff Formation. Geochronology of this region, A similar, southwest increase in metamorphic facies has also been reported east of the map area in the Dewar Lakes region (Jackson and Morgan, 1978; Tippett, 1984; Henderson et al., 1988). The field and laboratory study of metamorphic mineral reactions and assemblages in pelitic units of the Piling Group will form part of an ongoing Ph.D. thesis study by K. Dubach (Queen's University).

The metamorphic grade in the Piling Group gradually increases from greenschist to upperamphibolite facies, with K-feldspar+sillimanite+melt zone assemblages observed in metapelitic cover rocks located between Flint Lake and the MacDonald River. Corresponding assemblages in marble of the Flint Lake Formation (unit PPr) consist of tremolite+calcite+quartz ± *diopside*, in basalts, with the presence of the latter two phases dependant on bulk rock composition. The study of metamorphic mineral assemblages in the Flint Lake Formation marbles is part of an M.Sc. thesis study by D. Sinclair (Carleton University).

The fast deformation event of regional importance ($D_{1/2}$) resulted in orogen-perpendicular, kyanite-bearing, upright, open folds of all previously described Paleoproterozoic and Archean units. These folds interfere with $F_{3/4}$ folds to produce the current dome and basin map pattern in the project area. This fold interference is responsible for Archean(?) gneissoid domes in the southern portion of the transect and to the southeast (Henderson et al., 1988; Jackson, 2000). Kyanite-bearing assemblages are also observed in the Longstaff Bluff Formation (unit PHLp). The fabrics in the hills do not appear to have been accompanied by new metamorphic mineral growth. The fold interference pattern in the project area provides key structural relief for a study of the tectonostructural evolution of the orogenic margin by F. Bernolles (M.Sc. thesis; Queen's University) and 3D structural modelling by E. de Kemp (GSC; see also de Kemp et al., 2001).

METAMORPHISM

The lowest metamorphic grade in the Pre-Paleozoic rocks is uppergreenschist facies and it is characterized by biotite-muscovite-garnet-staurolite ± kyanite ± chloritoid assemblages observed in pelitic units of the Piling Group to the northwestis and southwards from there, with highest pressure-temperature conditions being reached in the southern part of the map area, where uppermostamphibolite to incipient granulite facies assemblages occur. To the north, metamorphic conditions reach middleamphibolite facies at most. With increasing regional metamorphic grade, the Longstaff Bluff Formation acquires biotite+muscovite+cordierite ± andalusite assemblages (melt pods absent in the lowest grade rocks). The first occurrence of K-feldspar+sillimanite ± garnet ± melt pods is observed in pelitic units of the Nadluardlak Lake in pelitic beds of the Longstaff Bluff Formation (unit PHLp) and appears to be produced by the reaction muscovite + plagioclase +quartz = sillimanite + K-feldspar + melt (see Spear, 1993, p. 366, and references therein). Approximately 15 kilometres further south, along an isograd that is roughly parallel to the one above (D.M. Carmichael, pers. com.), breakdown of biotite is observed through the vapor-absent reaction biotite + sillimanite + quartz = cordierite + K-feldspar + melt (see Spear, 1993, p. 366). This is the highest grade observed. This reaction eventually leads to production of large quantities of melt (unit PCgk) and we would suggest that, with the production of garnet ± cordierite bearing granitic plutons (unit Pggr). The spatial relationship between the Cumberland batholith and the highest metamorphic grades observed in the Longstaff Bluff Formation (unit PHLp), together with the emplacement of the garnet ± cordierite bearingunites (unit Pggr), suggests that heat input by intrusion of the batholith was responsible for the metamorphism of the Longstaff Bluff Formation. Geochronology of this region, A similar, southwest increase in metamorphic facies has also been reported east of the map area in the Dewar Lakes region (Jackson and Morgan, 1978; Tippett, 1984; Henderson et al., 1988). The field and laboratory study of metamorphic mineral reactions and assemblages in pelitic units of the Piling Group will form part of an ongoing Ph.D. thesis study by K. Dubach (Queen's University).

STRUCTURE

Regional deformation along the northern margin of Trans-Hudson Orogen on Baffin Island can be separated into four specific events. The earliest ($D_{1/2}$) is an Archean-age deformation event that was accompanied by middleamphibolite facies metamorphism. This event is observed in the Archean basement rocks and in the Piling Group supracrustal rocks within the basement. The original orientation and style of deformation of this tectonothermal event is obscured by younger, partitioned Proterozoic reworking and is best observed locally, where late-Archean intrusions (e.g. units Agt, Agr) crosscut highgrade fabrics preserved in the older units (see also Bethune and Scammell, 1997).

In the overlying lower sequence Piling Group, a number of low-angle repetitions of the Dewar Lakes and Flint Lake formations (units PHs, PHLs, PHLp, PHLb, PHv) are observed in the area of Flint Lake. Structural repetitions in the upper sequence Piling Group is more difficult to document due to the absence of regional stratigraphic markers within the Longstaff Bluff Formation, but it is nonetheless suggested by the presence of sharp, largescale fold limb truncations (Corrigan et al., 2001). Another important structural feature interpreted as $D_{1/2}$ is the juxtaposition of mafic pillowed units of the Bravo Lake Formation in the hangingwall and psammites of the Longstaff Bluff Formation in the footwall of the Nadluardlak Lake thrust fault. Locally, the thrust fault is characterized by a 50 to 100 metre thick mylonite zone at the base of the Bravo Lake Formation (described above), and by a flat-lying, geometrically supportive sill-mud contact. The $D_{1/2}$ event was both accompanied and outlined by regional metamorphic conditions, as suggested by the growth of peak metamorphic minerals. Emplacement of the Cumberland batholith must thus postdate the $D_{1/2}$ phase of the twonmca leucogranites (unit Pggr) which are potentially derived by partial melting of the Piling Group metasedimentary rocks, as well as the Archean basement, are observed to intrude the Longstaff Bluff Formation in the footwall of the Nadluardlak Lake thrust fault. Geochronology of these intrusions will form part of a Ph.D. thesis study on the petrology and petrogenesis of the Bravo Lake Formation by S. Modeland (McGill University).

The second Proterozoic event (D_2) was largely coaxial with $D_{1/2}$ and involved folding of the Archean basement and Piling Group supracrustal rocks. This event is observed in the Flint Lake area, where it is responsible for the overturned orientation of and recumbent folds with shallow, locally plunging axes (sections A-B, D-E). Garnet-muscovite-biotite ± tourmaline pegmatites associated with the emplacement of biotite granite (unit Pgr) along the northern margin of the Piling Group crosscut the $D_{1/2}$ fabric and are show evidence of metamorphism and deformation. The foliation observed in the biotite granite is parallel to the $D_{1/2}$ axialplanar foliation developed in the folded Piling Group supracrustal rocks. The D_2 event is also observed in the Nadluardlak Lake area, where it is responsible for the associated pegmatite overlapped with $D_{1/2}$. Other evidence pointing to D_2 being thick-skinned in the area is the broad parallelism observed between F_2 folds of the Piling Group cover and map-scale folds of the Archean basement in the Nadluardlak Lake area. Finally, the D_2 event is also observed in the Dewar Lakes area (NTS 27 B) and in the Eqe Bay area, supported by metadyke, which yields similar U-Pb ages in pegmatite within the Piling Group sedimentary rocks (ca. 1.81 Ga; Henderson and Henderson, 1994), in reworked Archean basement gneiss inliers (ca. 1.81 Ga; ibid.), and in reworked Archean gneiss immediately to the west of the present map area (ca. 1.82 Ga; Bethune and Scammell, 1997). A question that remains is the absolute timing between (1) the emplacement of the Cumberland batholith, (2) the emplacement of pegmatite and granite, and (3) emplacement of the northern biotite granite and (4) regional $D_{1/2}$ and D_2 deformations. These events appear to be strongly interrelated and may have occurred in sequence during a protracted period. Samples that will provide additional constraints on the timing of these events have been collected for U-Pb geochronology (N. Wodicka, GSC).

A set of steep, northdipping thrust faults striking approximately eastwest and occurring east of Piling Lake also deform the Archean basement and Piling Group rocks. These faults are interpreted as D_3 structures and are part of a northern domain comprising fewer structural levels exhi (Archean basement, Dewar Lakes and Flint Lake formations), crosscutting northern Paleoproterozoic plutonic rocks) against a southern domain comprising the upper sequence Astarte and Longstaff Bluff formations (sections A-B and B-C). The occurrence of the D_3 thrust faults is spatially coincident with an increase in the number and tightness of kilometre-scale folds of Longstaff Bluff Formation psammites and pelites in the southern and southern domains (see B-C).

In order to further document the structural evolution of the northern margin of the Trans-Hudson Orogen, and its relationship to the Archean basement and Piling Group cover, a Ph.D. thesis study by F. Bernolles (Queen's University) is constructing a set of detailed strike-perpendicular cross-sections from 70°N to 68°N. Construction of the sections is being done at 1:50 000 scale utilizing a downdigipe projection technique and adjusting for the variable plunges encountered in the project area due to $D_{1/2}$ cross folding (see below) of D_2 and D_3 axes.

CENOZOIC

QUATERNARY

PLEISTOCENE-RECENT

- Q — *Unconsolidated glacial drift with associated marine, lacustrine, fluvial, and bog deposits. Chiefly marine muds on coastal areas. Includes extensive felsenmeer in proximity to Barnes Ice Cap*

unconformity

PALEOZOIC

ORDOVICIAN(?) AND SILURIAN

UPPER (UPPER ORDOVICIAN (?) AND LOWER SILURIAN (LLANDOVERIAN)

- Osd — *Calcareous dolostone, dolostone, dolomitic limestone; minor calcareous and dolomitic breccia and flat-pebble conglomerate*

ORDOVICIAN

UPPER LOWER AND LOWER MIDDLE ORDOVICIAN

- Ols — *Dolomitic limestone; minor calcareous dolostone*
- Os — *UPPER POINT FORMATION: dolostone, in part sandy, silty, argillaceous; dolomitic flat-pebble conglomerate; minor dolomitic sandstone, siltstone, breccia, quartz-cemented sandstone*

unconformity

PROTEROZOIC

PALEOPROTEROZOIC

- Pum — *Ultramafic rocks; serpentinized peridotite and hornblendite; foliated to schistose; dark green or brown weathering*
- Pgr — *Biotite-allanite ± hornblende monzogranite, granodiorite; commonly grades into biotite-allanite ± hornblende monzogranite, granodiorite; massive- to coarse-grained, pink to white; abundant crosscutting veins and sheets of associated biotite-muscovite-garnet pegmatite and granite; locally contains abundant inclusions of layered psammite (unit Agn), quartz diorite, psammite (unit PPc), and marble (unit PPr); local weak foliation*
- Pggr — *Biotite-garnet ± muscovite ± sillimanite (fibrolite) ± cordierite synorogranite; leucocratic, medium- to coarse-grained to pegmatitic, white to light pink, massive to moderately foliated; contains abundant inclusions and rafts of high grade psammite, semipelite (unit PPd), possibly derived by partial to total melting of Piling Group sedimentary rocks (see descriptive notes)*

CUMBERLAND BATHOLITH (units PCgk - PCgr)

- PCgr — *Biotite ± garnet monzogranite, commonly grades into biotite synorogranite; massive, medium- to coarse-grained, grey to pink; varies from weakly to strongly foliated; locally contains rafts and inclusions of K-feldspar megacrystic monzogranite (unit PCgk)*
- PCgk — *Biotite ± hornblende ± garnet K-feldspar megacrystic monzogranite, granodiorite; dark to light pink, coarse-grained, commonly with aligned K-feldspar megacrysts; quartz, biotite; varies from weakly to strongly foliated; K-feldspar megacrysts commonly rimmed by plagioclase (Rapakivi texture); contains inclusions of high-grade psammite (unit PPv,g) (Longstaff Bluff Formation)*

intrusive contact

PILING GROUP (units PPd - PPs)

Upper Sequence

- PPs — *BRAVO LAKE FORMATION: basalt; pillowed, fragmental and massive flows; light to dark green, mafic and ultramafic cumulate sills; minor wacke, metre-scale layers of volcaniclastic sedimentary beds; millimetre- to centimetre-scale laminations, dark grey to white; minor psammite and semipelite; gabbro; peridotite; layered peridotite-gabbro sills*

tectonic contact

- PPLg — *LONGSTAFF BLUFF FORMATION (metamorphic mineral units PHLb - PPLg): Psammite, semipelite, pelite, arkosic- and lithic-wacke; interbedded; thin to thick bedded; light to dark grey; graded beds; minor hornblende-bearing calcsilicate beds and concretions; biotite-muscovite-garnet ± andalusite metamorphic assemblages; locally includes beds of biotite-allanite ± hornblende monzogranite, granodiorite, synorogranite and associated biotite-muscovite-garnet ± tourmaline pegmatite*

- - - mineral isograd - - -

- PPLs — *Psammite, semipelite, pelite, arkosic- and lithic-wacke; interbedded: thin to thick bedded; light to dark grey; graded beds; minor hornblende-bearing calcsilicate beds and concretions; biotite-allanite-K-feldspar ± melt pod mineral assemblages; locally includes beds of biotite-allanite ± hornblende monzogranite, granodiorite, synorogranite and associated biotite-muscovite-garnet ± tourmaline pegmatite*

- - - mineral isograd - - -

- PPLc — *Psammite, semipelite, pelite, arkosic- and lithic-wacke; interbedded; thin to thick bedded; light to dark grey; graded beds including inverse metamorphic grading; minor hornblende-bearing calcsilicate beds and concretions; biotite-muscovite-cordierite ± andalusite metamorphic assemblages; locally includes beds of biotite-allanite ± hornblende monzogranite, granodiorite, synorogranite and associated biotite-muscovite-garnet ± tourmaline pegmatite*

- - - mineral isograd - - -

- PPLb — *Psammite, semipelite, pelite, arkosic- and lithic-wacke; interbedded; thin to thick bedded; light to dark grey; graded beds; minor hornblende-bearing calcsilicate beds and concretions; biotite-muscovite ± garnet mineral assemblages*
- PPLa — *LONGSTAFF BLUFF FORMATION: Arkosic- and lithic-wacke; interbedded with psammite, semipelite, pelite; thin to thick bedded; white, gritty surface; graded beds; minor hornblende-bearing calcsilicate beds and concretions; biotite-muscovite ± garnet mineral assemblages*
- PPA — *ASTARTE RIVER FORMATION: sulphidic schist; rusty weathering; graphitic, pyrrhotite-pyrite schist and slate; sulphide facies iron formation*

Lower Sequence

- PPF — *FLINT LAKE FORMATION: marble, dolomite and calcsilicate; chiefly white to grey or buff weathering; massive beds, quartzite and calcsilicate facies iron formation; locally includes bodies of biotite-allanite ± hornblende monzogranite, granodiorite, synorogranite and associated biotite-muscovite-garnet ± tourmaline pegmatite*
- PPD — *DEWAR LAKES FORMATION: quartzite and feldspathic quartzite, semipelite; grey, white, and black; laminated to massive beds; locally cross-bedded; may include magnetite rich laminae; locally includes iron formation; chiefly oxide facies with silicate facies interbeds; grey- to cream-weathering; laminated to bedded; may include marble, dolomite and calcsilicate; locally includes bodies of biotite-allanite ± hornblende monzogranite, granodiorite, synorogranite and associated biotite-muscovite-garnet ± tourmaline pegmatite*

unconformity

ARCHEAN

NEOARCHEAN

- Agb — *Hornblende-biotite ± clinopyroxene gabbro; dark, medium- to coarse-grained; ophitic- to sub-ophitic texture; locally foliated to amphibolite*
- Agk — *Biotite ± hornblende K-feldspar megacrystic monzogranite, granodiorite; pink to buff; K-feldspar megacrysts in a finer-grained matrix of plagioclase, quartz, biotite ± hornblende; varies from weakly to strongly foliated, locally an L-tectonite; gradational into granitic and granodioritic rocks lacking megacrysts*
- Agr — *Biotite monzogranite, synogranite; pink, fine- to medium-grained; massive to moderately foliated; locally grades into megacrystic granite*

MARY RIVER GROUP (units Amb - Amp)

- Amp — *Psammite, semipelite; grey- to rusty-brown, flaggy; centimetre- to metre-scale laterally continuous layers; abundant melt pods; local interlayers of quartzite, pelite and iron formation*
- Amb — *Hornblende-biotite ± clinopyroxene amphibolite; fine- to medium-grained; alternating millimetre- to centimetre-scale black and green layers; metre-scale layers of coarser-grained amphibolite, semipelite and pelite; may be derived from a volcanic protolith and associated sedimentary rocks*
- Agn — *Biotite ± hornblende quartzofeldspathic orthogneiss; leucocratic gneiss of plutonic origin; granodioritic to monzogranitic; alternating grey to white, black, pink, fine- to medium-grained; moderately to well foliated, locally layered with concordant synorogranitic leucosome; locally contains amphibolite and tonalite bands, gabbro/anorthosite boudins; locally migmatitic*

limit of field work, 2000

- bd — *Bedrock areas not mapped during the summer of 2000*

Geological contact (defined, approximate)
