Till geochemistry results, central Baffin Island, Nunavut (NTS 37A, 37D, 27B, 27C)

Introduction

A regional-scale drift sampling survey was carried out in central Baffin Island as part of a GSC-CNGO collaborative project to map and understand the geology of this part of Nunavut. Paleoproterozoic supracrustal rocks of the Piling Group, prospective for several different mineral deposit types (Scott et al., 2003), are extensively covered by Quaternary sediments. Drift sampling therefore provides a valuable tool for mineral exploration in this remote region.

The Quaternary geology component of the Central Baffin Project was designed to provide a regional framework for geologic interpretation, sustainable development, environmental management, and drift prospecting in NTS areas 27B, C, and 37A, D (Fig. 1). The field programme involved helicopter-assisted ground work, including surficial geology mapping at a scale of 1: 100 000, till sampling, clast identification, and measuring of ice-flow indicators. About 750 2-kg samples were collected for trace and major element chemistry, textural analysis, and carbonate determinations.

The purpose of this report is to release geochemical and clast lithology data from the till sampling programme. The data establish regional background concentrations of selected elements for resource development and environmental baseline studies; and indicate which areas have anomalous concentrations of elements that may be of interest to mineral exploration.

The report presents the regional geologic setting, including a brief overview of the Quaternary ice-flow history. Sampling methods, and laboratory procedures used for analyses and quality control are described. The appendices contain sample location information, results of geochemical analyses of the <0.002 mm (clay) size fraction analyzed by inductively coupled plasma – atomic emission spectrometry (ICP-AES), and of the <0.063 mm (silt + clay) size fraction analysed by instrumental neutron activation analysis (INAA), platinum group element results, quality control data, and summary statistics for each element. Grain size information, and data on pebble counts, useful for assessing glacial transport distances, have also been included.

Interpretative reports and surficial geology maps for this region, complementary to this data release, are published separately (Dredge, 1999, 2002a, 2003). A final report containing a more complete interpretation of the glacial and postglacial evolution of the region, and of the data presented here, will be published later.

Regional Setting

The project lies in the central part of Baffin Island, and extends from Foxe Basin in the west, across the Barnes Ice Cap, to the headlands of fiords along the coast of Baffin Bay in the east (Fig. 1). The area is part of a tilted surface rising towards the northeast. It can be divided into three broad physiographic regions: coastal lowlands adjacent to Foxe Basin, a central upland plateau forming the spine of Baffin Island, and a cliffted fiord coast along the northeast rim. Elevations range from near sea level on the islands in Foxe Basin and coastal areas around Wordie Bay in the southwest, to 1370 m in the

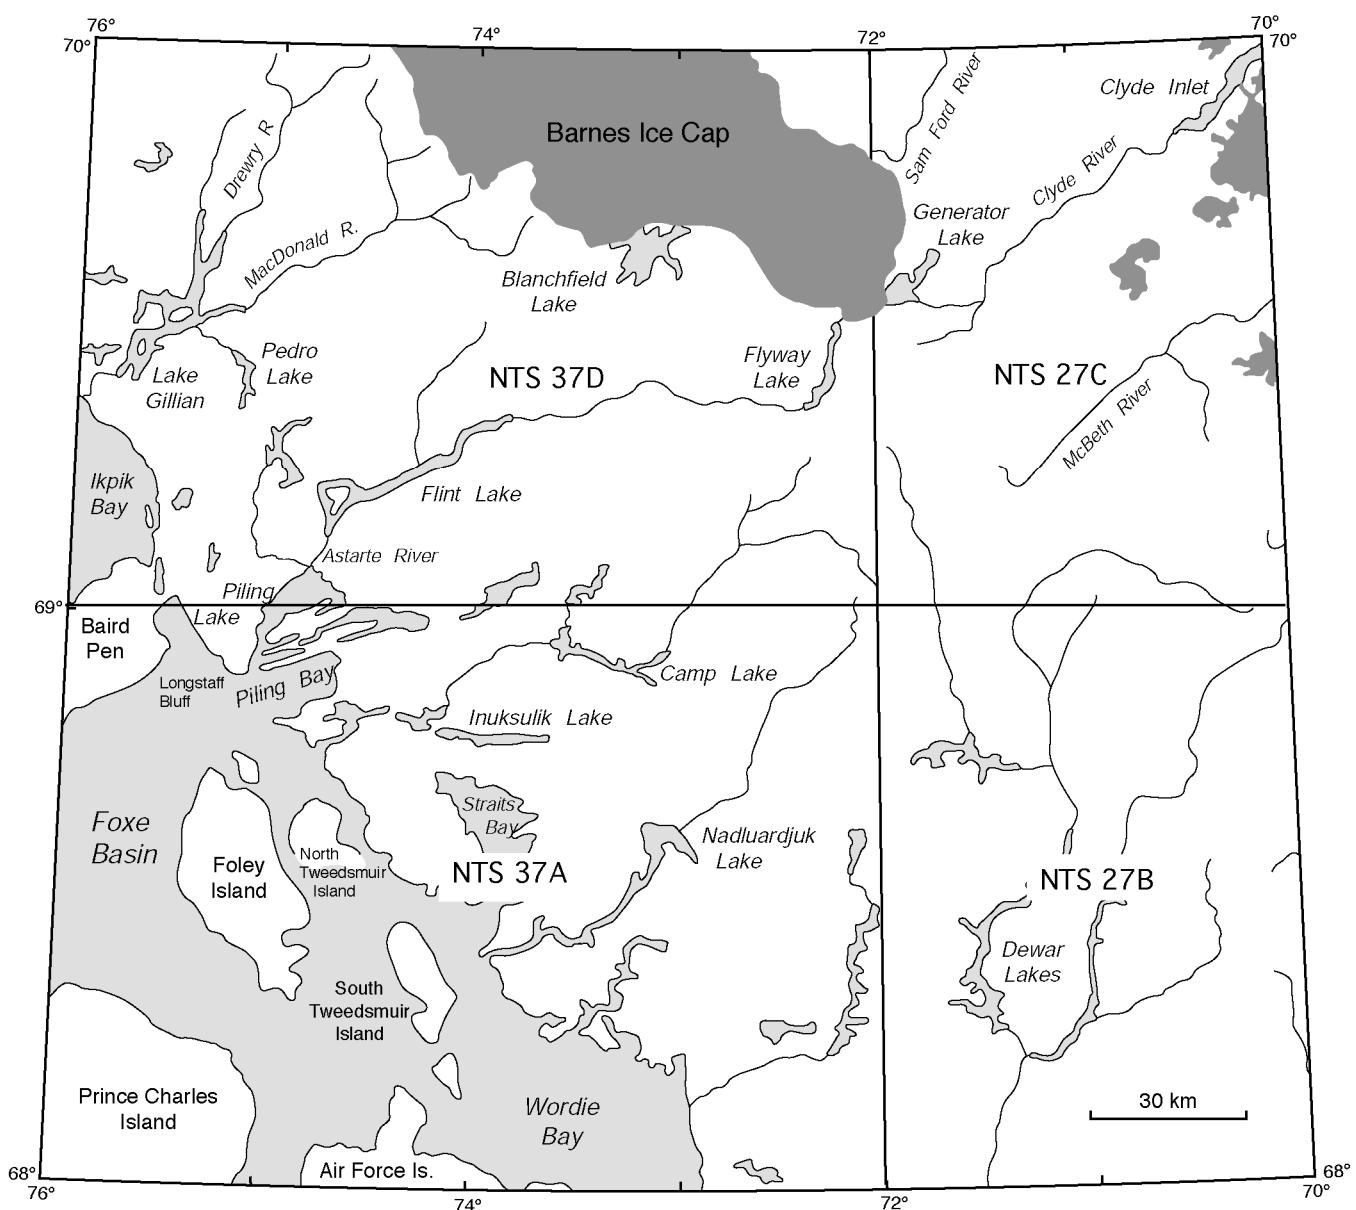

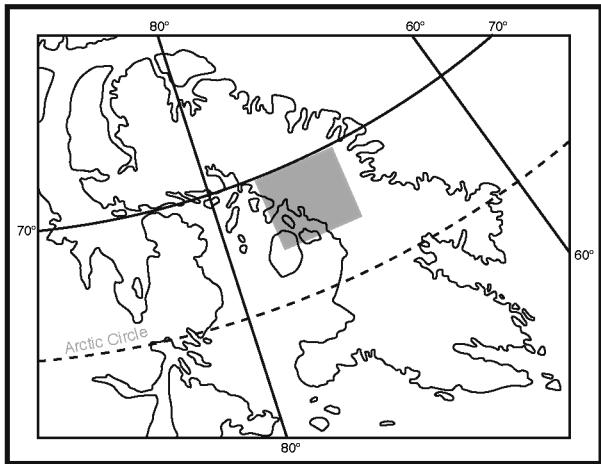

Figure 1 Location of the project area

northeast. The central plateau lies at an elevation of about 600 m in the north, and declines to about 420 near the southern limit of the map area. The south dome of the Barnes Ice Cap, and the main part of the central plateau lies at about 915 m, although the main glacier dome rises to 1060 m, and local ice caps above the fiords reach elevations of 1370 m. Most rivers and streams flow southwest into Foxe Basin. Only short streams, and the McBeth, Clyde, and Sam Ford rivers flow toward Baffin Bay.

The area lies within continuous permafrost. Summer thaw depths range from about <10 cm near the Barnes Ice Cap, to more than 2 m in wetlands near Foxe Basin. The depth of thaw, which is a limiting factor for sampling till, is commonly about 50 cm.

Bedrock geology and mineral potential

The area straddles the southeastern margin of the Rae craton on Baffin island (Scott et al., 2002, 2003). Major deformation and metamorphism occurred during the 1.8 Ga Trans-Hudson orogeny. Initial mapping of the north half of the map area by Morgan (1981) and Henderson (1985) broadly delineated a series of formations of Archean and Proterozoic age. Recent detailed mapping of a broader area (Scott et al., 2002, 2003; St-Onge et al. 2004) has increased coverage and has resulted in a more complete understanding of the bedrock geology.

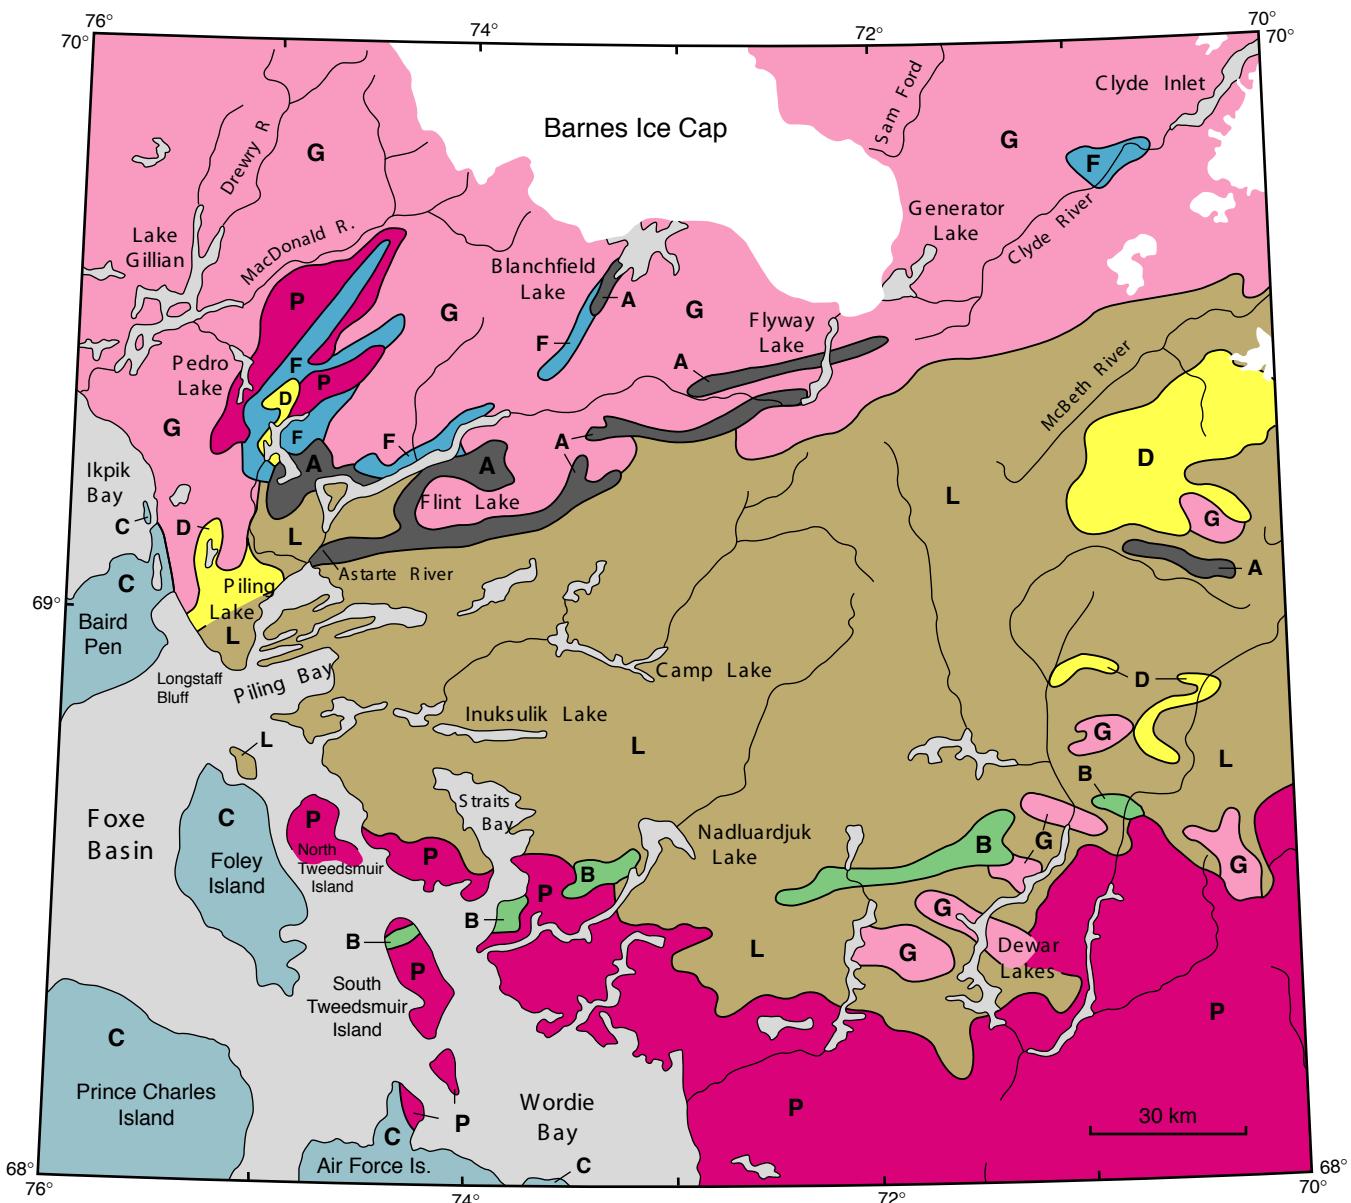

In summary, the northern part of the area contains Archean granitic and gneissic rocks of the Rae Craton (Fig. 2), and includes minor psammitic and amphibolite units of the Mary River Group (Scott et al., 2003). A central belt, called the Piling Group, represents a continental margin succession containing both supracrustal and volcanic rocks. The stratigraphically lowest unit of quartzite (Dewar Lakes Formation) is overlain by dolostone and marble (Flint Lake Formation). Mafic to ultramafic volcanic bodies and sills (Bravo Lake Formation) occupy the same relative stratigraphic position as the carbonate beds, and are confined to the southern part of the map area. Both the Flint Lake and the Bravo Lake Formations are overlain by rusty weathering graphitic pelite containing pyrite and pyrrhotite (Astarte River Formation). The uppermost unit of the Piling Group comprises a thick sequence of psammite and semi-pelite, with minor calc-silicate pods (Longstaff Bluff Formation) deposited as a molasse. Proterozoic plutonic rocks intrude the Piling group. The largest body consists of K-feldspar megacrystic monzogranite of the Cumberland batholith in the southernmost part of the map area. Small syenogranite pegmatite bodies containing muscovite occur throughout the area, particularly north of Longstaff Bluff and east of Wordie Bay. Northwest-trending diabase dykes of the Franklin swarm are also common.

The Proterozoic rocks hold potential for a variety of mineral deposit types (Scott et al., 2003), including Zn (Flint Lake Fm), SEDEX base metals (Astarte Fm), Ni-Cu-PGE (Bravo Lake Fm), Pb-Zn-Ag and Au (upper Dewar lakes Fm), and Sn-Ta (Longstaff Bluff Fm). Areas to the north of the project area are currently being prospected for diamonds.

Baird Peninsula, and the flat-lying islands in Foxe Basin are underlain by Paleozoic limestone and dolostone.

Quaternary geology

Mapping in this area began with the work of the Geographical Branch, when V.W. Sim (1964) showed the distribution of surface materials and glacial features at a scale of

1:500 000 for NTS areas 37A and 37D. Systematic, more detailed field work across the entire report area in 1998, 2001, and 2002 during the collaborative GSC-CNGO project resulted in a set of surficial geology maps at a scale of 1:100 000 (Dredge, 2003a-l), and short papers on glacial history and emergence (Dredge, 1999, 2002a). Between these two projects, an extensive lake sediment sampling programme was executed (Friske et al., 1999).

Ice flow history

Early field work (Andrews and Sim, 1964), recent cosmogenic dates (Coulthard et al., 2003) and ice-mass models have suggested a major flow of glacier ice across Baffin Island from Foxe Basin before and during the last glacial maximum (LGM). Tippett (1985) and results of field work from this project indicate that an ice stream carried carbonate drift across the peninsula from Wordie Bay to Ekalugad Fiord across relatively low terrain, but that limestone indicators relating to Foxe Ice do not extend far inland in other areas. It is possible that Foxe ice was cold-based for most of the LGM. Striations (Fig. 3), indicator erratics, and landforms suggest later glacial flow from a Baffin ice centre. The prevalence of weathered rock, lack of ice-scoured lake basins, and absence of striations on the central plateau suggests that the island spine was a major ice divide, and that ice flowed out towards the two coasts. Baffin Ice may have been cold-based much of the time, producing rubble fields indicative of short-distance glacial transport. Striations, roches moutonnées and sharply defined swaths of eroded bedrock indicate that Baffin-centred ice was warm-based at some places and at some times, transporting till for greater distances. Crossing striations indicate that the ice-flow centre gradually shifted northwestwards towards the present Barnes Ice Cap, and that ice tongues located in valleys flowed towards both coasts during ice recession.

Deglaciation began more than 9200 years ago (GSC-707) in the eastern outer fiords. Massive upland end moraines (Cockburn Moraines) developed along the eastern part of the field area, crossing the heads of fiords about 8000 years ago (I-1932 Clyde Fiord; I-1602 Inugsuin Fiord; Fig. 4), when sea level was about 50-60 m above present. The Foxe Basin coast became ice-free about 6700 years ago (I-406 at 90m; Sim, 1964) when sea level stood at 110 m. Other large end moraines on the plateau, ice-dammed glacial lakes with sublacustrine moraines, and stacked sets of meltwater channels trace the pattern of ice recession towards and along the central plateau, and the recession of ice tongues from major valleys towards the Barnes Ice Cap.

Lichen-free zones on the east side of the field area and around the west side of the Barnes Ice Cap denote areas of snow and icefields during the Little Ice Age.

Surficial Materials

Figure 4 is a generalized surficial materials map based on the detailed maps listed in the references (Dredge, 2003).

Rock outcrop

Rock outcrop forms extensive surfaces in the northern and southern parts of the region, where granite and gneiss are the dominant lithologies. Fresh cliff faces form the walls of the deep valleys opening into the eastern fiords, and along the Drewry River, McDonald River, and arms of Gillian and Flint Lakes. Glacially scoured bedrock surfaces form linear swaths along the Sam Ford, Clyde and McBeth Rivers east of the Barnes Ice Cap.

Figure 4. Surficial materials

East-west trending outcrops are common along valley walls and scarps within the Piling Group west of the central plateau. Rock outcrop in the south-central area is substantially weathered, and the weathering byproducts lie over outcrop surfaces.

Till

Till covers most of central Baffin Island. For this project the till has been divided on the basis of thickness into till veneer (T_v on the maps), till blanket (T_b), hummocky till (T_h), and major moraines (T_m). The till surfaces are covered with mudboils, the features used for geochemical sampling. Till veneers are thin (<2 m thick) and discontinuous covers of till containing substantial amounts of rock outcrop. Underlying rock structures are visible. This till unit tends to be more stony or bouldery than till blanket deposits, and has probably been glacially transported for shorter distances. Till blanket units form rolling terrain with till thicknesses ranging from 2 to 10 m. Small outcrops protude through the till cover in some places. Hummocky till and major moraines occur primarily in the northeast and central parts of the map area. The moraines are commonly >20 m thick, and mark recessional positions of the Baffin Ice mass. Large ice-wedge polygons and solifluction lobes on these surfaces suggest buried ground ice or relict glacial ice in the subsurface. The location of smaller end moraines and sublacustrine moraines are shown on the 1:100 000 scale maps of the region by symbols.

The character of the till is directly related to rock types and ice dynamics. Sharply defined changes from scoured rock to till blankets are indicative of changes from erosive to depositional basal ice regimes. Except for the Wordie Bay carbonate train, an indicator of long distance transport, the till reflects closely the composition of the underlying bedrock. Till over granite and gneiss tends to have a sandy matrix with relatively few fine materials. Boulderfields are common in the northern landscape, and mudboils are poorly developed where fine material is lacking. Till over the Piling Group rocks has a silty sand matrix and well-developed mudboils. Boulder content is generally low, but some boulderfields have developed by frost riving where cleavage angles and bedding planes are near vertical. Boulderfields or weathered surfaces with grus are common in the south in areas underlying the Baffin Ice divide, where basal ice transport was minimal.

Kames and outwash

Kame deposits are scarce in the area, but gravelly outwash is prevalent along major river valleys in the northern half of the map area.

Glacial lake deposits

Glacial lake deposits occur where meltwater was ponded between heights of land and the ice margin on the eastern side of the study area. The deposits consist of drapes of sand or silt less than 2 m thick, interspersed with small (sublacustrine) moraines in the north, particularly around the existing Barnes Ice Cap. In the southeast, the lacustrine deposits within glacial lake basins are very thin, and most of the material consists of washed till surfaces with boulder lag deposits.

Postglacial marine deposits

On the west side of Baffin Island, raised marine deposits cover the islands in Foxe Basin and Baird Peninsula, and extend inland from the east coast for distances of 1 to 4 km in the north, and as much as 30 km inland in the south. Widespread marine deposits form lowland wetlands having a substrate of stony silt and sand, but flights of flaggy limestone or granitic cobble beaches flank large scarps that trend parallel to the west side of the

island. Marine deposits extend to an elevation of 110 m near the west coast but only to about 60 m ASL at Nadluardjuk Lake farther inland. On the east side of the island marine deposits are limited to the heads of fiords, where they form terraces and deltas of clayey silt and sand. These occur up to an elevation of 68 m within the map area, but most are below 30 m ASL.

Methodology

Sampling methods

A survey strategy was devised to obtain representative, approximately evenly spaced samples from across the entire study area, a general practice in reconnaissance surveys (McMartin and McClenaghan, 2001).

Samples of 2 kg size were collected for trace, major and minor element geochemistry. Till was used as the sampling medium, and samples were taken from the walls of pits dug into mudboils. Most samples were taken from depths ranging from 20 to 50 cm. Care was taken to avoid obvious oxidation or organic layers. The frost churning that creates mudboils brings up fresh material from unoxidized subsurface sediment and homogenizes material throughout the mudboil. Studies by Schau (1983) and Pehrsson (2002) on mainland Nunavut indicate a close relationship between the chemical composition in the mudboils and that of the underlying bedrock. The same relationship between till and bedrock should apply to most of central Baffin Island, where local tills are prevalent.

A total of about 764 samples were collected for till analysis over an area of about 45 000 km² during the field seasons of 1998, 2001, and 2002. Sample locations are shown on Figure 5, and co-ordinates are given in Appendix I. Additional samples were taken in areas where gossans were mapped. In particular, gossanous material and adjacent unweathered till pairs were sampled so that fresh samples in areas of potential mineralization could be examined (cf Dredge, 2002b). The gossan samples are listed with a "G" suffix in the data tables. In addition to matrix sampling, sets of 50 pebbles, each ranging in size from 1 to 4 cm, were collected from mudboils sampled for geochemical analysis, and were classified according to lithology.

Laboratory preparations and analytic procedures

Preparations in the Terrain Sciences Sedimentology Laboratory follow those described by Klassen et al. (2000), and detailed sampling and analytic procedures have been described by McMartin and McClenaghan (2001). For this project, two size fractions were analysed: the clay fraction (< 0.002 mm), and the silt + clay fraction (<0.063 mm).

The clay size is especially useful for detecting elements such as Cu, Pb, and Zn (Klassen, 2001), that occur preferentially in clay sizes, and for those elements that occur in rock types, such as pelites, that are glacially ground to clay-sized material. In addition, glacially produced lattice irregularities in the clay-sized minerals, even non-phyllosilicates, tend to adsorb cations better than coarser materials, thus accentuating the concentrations of metals, and emphasizing the contrast between background and anomalous concentrations of elements. The silt + clay fraction was used to pick up elements that do not occur in the clay fraction (e.g. Au), or for samples that contain

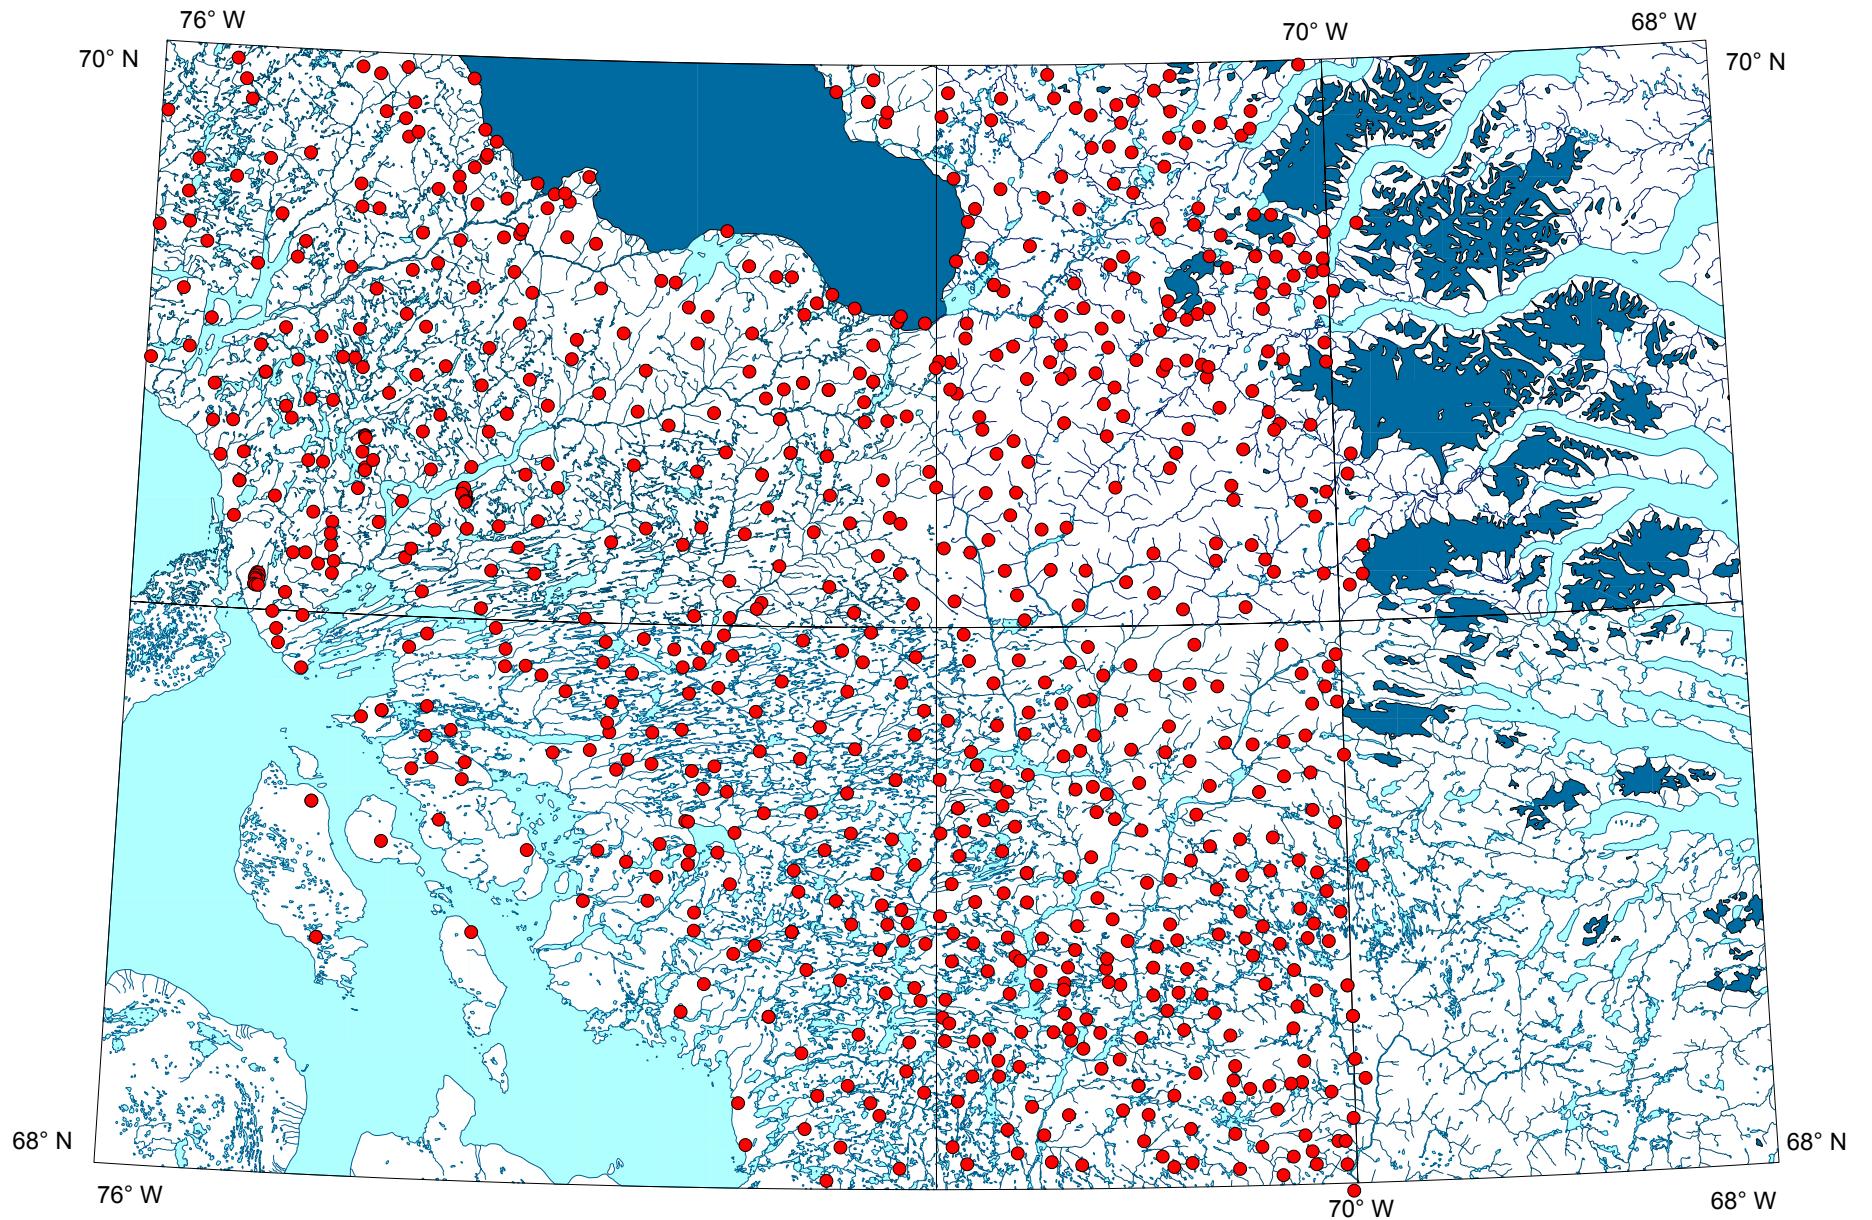

Figure 5 Location of till samples

insufficient clay material. This size fraction is the one most commonly chosen by industry.

Detection limits for elements are shown in Table 1, and results for both the ICP analyses and the INAA analyses are presented in the appendices. Element concentrations below the detection limit are listed in the appendices at half the detection level for the calculation of summary statistics.

ICP analyses

500-gram splits from bulk till samples were centrifuged and decanted to obtain the clay-sized (<0.002 mm) fraction. 5-gram aliquots of the clay material were then analyzed for selected trace and major elements using inductively coupled plasma – atomic emission spectrometry (ICP-AES) at ALS Chemex laboratory, Mississauga, Ontario. All the clay-sized samples were digested in an aqua-regia solution (3HCl:1HNO₃) prior to analysis in order to break down organic matter, salts, phyllosilicates, sulphides, and most silicates; this digestion may be incomplete for aluminum, barium, beryllium, calcium, chromium, gallium, lanthanum, magnesium, potassium, scandium, sodium, strontium, thallium, titanium, and tungsten. Analytic results and related statistics are reported in Appendices II, III, and IV . In all samples, tungsten was below the detection limit. Phosphorous results are erroneous due to the addition of sodium metaphosphate as a deflocculant.

For 133 selected samples, gold, platinum and palladium concentrations were analyzed by fire assay – ICP-ES on the <0.063 mm fraction at the ALS Chemex lab. Most of these samples overlie or surround the Bravo Lake Formation.

INAA analyses

The silt+clay size fraction (<0.063 mm) of the till was prepared by dry sieving at the GSC and sent to Activation Laboratories Ltd., Ancaster, Ontario for irradiation and analysis using Instrumental neutron activation analysis (INAA) on approximately 30 gm aliquots. This method is particularly sensitive for rare earth elements (La, Ce, Nd, Sm, Eu, Tb, Yb, and Lu), and Sc, Co, Cr, Cs, Hf, Ta, Th, U, and Au. Geochemical results for 35 elements are presented in Appendices V and VI. For all samples, Hg, Ir, Ni, Sn and Sr concentrations were below detection limits.

Pebble lithologies

Clasts from the surfaces of mudboils were classified into eight different rock types that were easily recognized in the field. These data, shown in Appendix IX as percent counts, aid in the interpretation of the geochemical data, and in assessing till transport distances.

Textural data

Textural analyses on samples were completed by dry sieving sample splits for the size range between 4 mm and 0.063 mm. Silt and clay fractions were determined with a particle size analyzer (Klassen et al., 2000). The results are given in Appendix X.

Other analyses and sample archiving

Additional analyses, not included in this report, were performed on the till samples.

1) Carbonate analysis. 3-gram aliquots of the <0.063mm fraction were used to determine inorganic and organic carbon using a Leco Cr-412 analyzer. An interpretation of the carbonate results will be presented separately.

2) In addition to ICP and INAA analyses, all till samples were analysed for U, Th, and K by gamma ray spectrometry. Comparative results between laboratory determinations of various size fractions, and with airborne and ground spectrometry data will be presented in a separate report.

3) About 500 g of each bulk till sample were archived.

Quality control

Accuracy of geochemical analyses was monitored using GSC till standards (TCA 8010), and the CanMet certified standards (Till-2, Till-3) according to procedures established by the GSC Sedimentology Laboratory (Klassen et al., 2000). The standards were inserted into the sample set at regular intervals. Analytic precision was established by analysis of sample duplicates (subsamples). Several field sites from 2001 were also resampled in 2002, and the results were compared with those analysed the previous year. Quality control results are listed in Appendices VII and VIII.

Accuracy is good for most elements, and standards are within acceptable limits, although there is a consistent downward drift of about 15% in element concentrations in the ICP-AES analyses for this project, relative to the independent standards. Accuracy is good for INAA results on most elements that are above their minimum detection limit, and are within 15% of expected values. However, arsenic values are consistently slightly above standard values, and nickel and zinc show considerable variation in consecutive runs of the standard.

Analysis of duplicate splits from the till samples are generally in good agreement with the originals for elements above detection limits. The duplicate ICP-AES results suggest that precision is low for Bi, Ga, and for elements near the lower detection limit, specifically B, Cd, Hg, Sb, Tl, Pd, U, and W. The precision is good for other elements. INAA duplicates indicate that precision is good for most elements, but that Mo, Ni, Tb, W, and perhaps Zn values should be interpreted with caution. Precision is also low for Au, Ca, Eu, Sr, and Ta, which have most values near the lower detection limit.

Acknowledgements

This report is part of the Central Baffin Project and the Trans-Hudson Orogeny Project, which were jointly funded by Geological Survey of Canada, Canada-Nunavut Geoscience Office, and Polar Continental Shelf Project. Polar Continental Shelf Project assisted with helicopter and fixed wing field support. I would like to thank Ross Knight, Edward Little and the students on the Quaternary Geology team, who assisted with the collection of samples; Marc St-Onge and the Bedrock team for their logistical support and discussions in the field; and the GSC Sedimentology Lab for preparation and handling of samples. Thanks also to Isabelle McMartin and Marc St-Onge for critical reviews of this manuscript.
