DESCRIPTIVE NOTES

INTRODUCTION

The accompanying map presents the preliminary geology of the Meadowbank gold deposit area, examined as part of the Canada-Nunavut geoscience mapping project of the Western Churchill Natmap program. The map is a product of 1:5 000 to 1:20 000 scale mapping on foot traverse by Wilkinson, Zaleski, and others as cited. Previous and recent studies encompassing the area include 1:5 000 to 1:100 000 scale maps of Ashton (1988), Henderson and Henderson (1994), Jackson (1994), Jackson and Berman (1994), Jackson and Mazurski (1994), Henderson et al., (1991), Armitage (1992 and references therein), Armitage et al., (1995), Kjarsgaard et al., (1997), Kerswill et al., (1998), Zaleski et al., (1999a, 2000) and Sherlock et al., (2001c). Early regional reconnaissance maps include those of Heywood (1967), Fraser (1968), Wilson (1968) and Henderson and Brown (1966). Information from the authors also utilized archived data of Henderson (1982), the unpublished 1:20 000 scale map of Hughes and Legault (1991) and an unpublished report by Miller (1997).

The Meadowbank gold deposit is located 70 km north of Baker Lake, Nunavut, in the Rae domain of the Canadian Shield (Fig. 1). Access is by float plane or helicopter from Baker Lake in the summer or seasonally by winter road. Bedrock exposure is moderate to poor away from lakeshore and moderate to good on the shoreline and islands of Third Portage Lake. A summary of the geologic units is presented below, along with a description of structures, metamorphism, geochemistry, and mineral potential. No stratigraphic succession is implied by the order of Archean units described below. Unit names are informal, and are capitalized to distinguish them from general terms. Rock name is omitted from the legend and following descriptions. Phytographic names, including minor lakes, are informal.

GENERAL GEOLOGY

The Meadowbank deposit area is underlain by metamorphosed and polydeformed supracrustal rocks of the Woodburn group and two large domains of granitoid rocks. The Woodburn group is part of a 3000 km long Neoarchean supracrustal sequence stretching from northern Saskatchewan to Baffin Island in the Rae domain (Fig.1). The group comprises Neoarchean volcano-sedimentary rocks that have been divided into at least three distinct packages: 1) ca. 2.72-2.71 Ga ultramafic through felsic volcanic and volcaniclastic rocks with associated iron-formation; 2) quartzites, pelites, and greywackes; and 3) ca. 2.68 Ga mafic to felsic volcanic rocks and pelites, which are intruded by gabbro and also with interlayered iron-formation (Zaleski and Zaleski, 1998; Zaleski et al., 2001). Rocks of the Woodburn Lake group are polydeformed and have been overprinted by strong regional Paleoproterozoic deformation, possibly related to the Trans-Hudson orogen (Hoffman, 1988). The Paleoproterozoic deformation is responsible for the map pattern and results in a complex map pattern with multiple repetition of units. Low pressure-high temperature metamorphism that accompanied the second regional deformation event produced a zonation from mid-greenschist to amphibolite grade, from south to north (Kerswill et al., 1998).

The Meadowbank gold deposit, which includes the Third Portage, Goose Island, Bay zone, and North Portage zone, with an estimated combined resource of 7.1 million ounces (Table 1; Cumberland Resources Ltd, press release, March 2, 2004), is hosted by a package of Archean volcanic rocks and iron formation. This volcanic-dominated package (Zaleski et al., 1998a, 2001; Sherlock et al., 2001b), Archaean gold occurrences were first discovered in 1983 by Wolfex Exploration (a subsidiary of Comaplex Minerals Corp.). Joint venture partner Asamera further delineated the prospect through mapping and diamond drilling between 1986-87, when it was optioned by Agnico Eagle, Hecla Mining, and Lucky Eagle Mines. During the mid-1990's, partners Comaplex Minerals and Cumberland Resources carried out exploration programs on the property. Cumberland Resources, the sole owner since 1998, is presently pursuing additional gold prospects northeast of Tehek Lake.

THE WOODBURN GROUP

Volcanic and related rocks

The oldest supracrustal rocks of the Meadowbank deposit area are ca. 2.71 Ga volcanic, reworked volcaniclastic and related sedimentary rocks of the Woodburn group (Davis and Zaleski, 1998). Where exposure or data are insufficient to map out the entire succession, the volcanic rocks are divided into a lower, dominantly mafic volcanic-dominated unit, found west and southwest of Third Portage Lake (unit Awvc), A dearth of tuning directions and strong transposition of units precludes establishing an internal stratigraphic order within this succession.

The Lower Greenschist unit (Awvc) and the Middle Greenschist unit (Awvf) volcanic rocks make up the largest component of the volcanic sequence. The reworked volcaniclastic rocks are bedded to laminated wackes and tuffaceous wackes, characterized by sand to granule sized quartz eyes, subrounded to rounded plagioclase crystals, and lithic fragments of felsic volcanic rocks, in a fine grained, commonly chloritic and sericitic matrix (unit Awvcw). The lithic clasts comprise (in decreasing order of abundance): polycrystalline quartz (quartzite and possible vein quartz), quartz-plagioclase porphyry, tonalite-plagioclase porphyry, and rare polycrystalline pink-to-grey plagioclase aggregates, Bedding is defined by variations in the proportion of quartz eyes, the proportion of lithic clasts, and the proportion of suboxidized to oxidized plagioclase crystal clasts and quartz-plagioclase porphyry clasts and a compositionally more homogeneous, well-sorted matrix. Unit Awvc is interpreted as a reworked volcaniclastic deposit owing to the presence and abundance of quartz eyes, plagioclase crystals, and quartz-plagioclase porphyry clasts, the compositional similarity between the matrix and lithic clasts, and abundance or or locally observed gradational contacts with interlayered volcaniclastic conglomerate and wackes.

Laminated volcaniclastic wackes with amphibolite psuedomorphs (unit Awvcw) are restricted to the southern part of the map area, above the amphibolite zone boundary. They are interpreted as metamorphic equivalents of unit Awvc and unit Awvf. Unit Awvcw is mapped locally be difficult to distinguish from mafic volcanic where coarse, decussate amphibole obliterate the layering.

Felsic to intermediate volcanic rocks (unit Awvf) underlie the Dogleg Lake, Camp Island, and Horse Peninsula areas, and are found in the core of the Second Portage syncline and in the northeast part of the map area. They comprise pyroclastic and probable volcanic flows. The tuffs are characterized by embayed and more rarely bipyramidal Q-A-mm quartz crystals, broken and euhedral < 5mm plagioclase crystals, rare hornblende phenocrysts (pseudomorphed by actinolite) or biotite laplilli and crystals in a fine- to very fine-grained qtz-plag ± chl ± fe oxide matrix. Rare, poorly sorted, volcanic breccias with ~ 20% blocks supported by an aphanitic qtz-plag-mus ± chl groundmasses are noted on Horse Peninsula. The felsic volcanic rocks with up to 5% disseminated hornblende in the matrix or minor mm-thick layers with 40% hornblende are found throughout the unit.

Felsic volcaniclastic rocks and related rocks (unit Awvf) and the Second Portage Lake Complex (unit Awfq) are differentiated in the Second Portage and Tunnel Lake areas. These rocks are massive to layered and homogeneous, consisting of 2-5mm, euhedral quartz and plagioclase phenocrysts in an aphanitic to sugary mus-qtz matrix. They have been dated at 2681 ± 2 Ma (Zaleski et al., 2000; Zaleski et al., 2001; Zaleski and Sherlock) and may in part represent synvolcanic intrusions (see also Sherlock et al., 2001a, b).

Ultramafic volcanic and related rocks (unit Awkm) are present in two km-scale linear bands associated with iron-formation east of Third Portage lake, as a number of small, discontinuous horizons throughout the volcanic stratigraphy, and as generally narrow lenses at the contacts of iron-formation or quartzite. The unit consists predominantly of massive to spinifex-textured komatiite flows and sills, and minor, thin, komatiitic basalt flows and tuffs. The komatiitic flows comprise (in decreasing order of abundance) actinolite-tremolite-chlorite komatiitic and basaltic komatiite flows and breccia, Buff-cream dolomite-quartz-ankerite schists adjacent to the East BIF and just north of Third Portage Lake are strongly foliated and lineated, and may be in part tectonic in origin. Interlayered with the ultramafic rocks are minor, thin, graphitic, cherty, manganiferous sediments. Rare primary textures include spinifex texture and polyhedral jointing. Layering on a cm- to dm-scale is defined by grain-size and compositional variations in amphibole and talc content.

Mafic volcanic flows and related rocks (unit Awmv) are found in the Second Portage Lake and Amarulik Lake areas, but particularly thick occurrences are found adjacent to quartzite at the north end of Third Portage Lake and between two quartzite panels extending from Third to Second Portage Lakes. These rocks consist of subordinate, 2-4 mm plagioclase crystals and quartz-feldspar porphyry felsic clasts in an ultramafic to mafic matrix of foliated chlorite and carbonate, y minor quartz or plagioclase. Rare fine-scale beds with pebbles or granules of quartz-feldspar porphyry have been noted, suggesting the unit represents tuffaceous to reworked mafic-ultramafic volcaniclastic rocks.

Mafic volcanic flows and related rocks (unit Awmf) typically form only minor lenses within the ultramafic rocks, but are more abundant in the Second Portage Lake area, where they are found as a number of thick, discontinuous mafic volcanic rocks. They are fine- to medium-grained, massive greenish schists or schistose amphibolites that locally display km-scale amphibole layering. Coarser-grained flows can be difficult to distinguish from gabbros, as they have similar textures and mineralogy, but lack cumulate textures. Primary structures are rare, although deformed pillows are noted on an island in southwest Third Portage Lake.

Metagabbroic rocks, including gabbro and pyroxenite, (unit Awg) are often associated with the mafic volcanic flows and are interpreted as sills. Unit Awg is found in the Second Portage Lake area and in a number of small bodies elsewhere. The gabbros are typically massive but locally have 0.5-1 cm, sub- to euhedral plagioclase phenocrysts and display a relict diabasic, ophitic or subophitic texture. The sill-like intrusions within unit Awvc have sharp contacts with adjacent host rocks and are interpreted as synvolcanic sills related to the mafic flows on the basis of a similar geochemical signature. A large composite mafic intrusion between southwest Tern Lake and Third Portage lake has a crude layering and is interpreted as a synvolcanic intrusion related to overlying mafic flows. This unit is distinguished from unit Agt on the basis of its plagioclase-phyric texture and geochemistry.

A variety of chemical and clastic sedimentary rocks are found as dm- to 10's m-scale beds or mappable units within the volcanic sequence (unit Awsm). Most of these rocks are found in the Second Portage Lake area, where, as the most widespread, found as discontinuous thin (up to 10 m wide x 3 km long) interbeds throughout the sequence, but form thicker (10-100's m) units traceable for 10's of km at the contacts between ultramafic (unit Awkm) and felsic volcanic rocks (unit Awvf) and mafic volcanic rocks (unit Awmf). The most abundant sedimentary rocks are cherts (unit Awp). The thickest units are known as the East, West, and Central BIF (Banded Iron-Formation) (Armitage et al., 1995), of which the latter hosts the Meadowbank deposit, iron-formation characteristically contains cm- to m-scale chl ± grt ± cum ± anth ± gru ± mt ± po ± py ± cpy ± sph ± ank ± cc ± qtz bands and layers. Magnetite is rare to absent, beds in the iron-formation are defined by mm- to dm-thick, alternating quartz- or magnetite-rich cummingtonite-rich bands, Sulphidic iron-formation, consisting of quartz-magnetite-pyrrhotite ± arsenopyrite, is typically found where the iron-formation is gold-bearing.

A quartz-rich, muscovite ± chlorite schist (unit Awmv) underlies much of the North Portage area and envelops the Goose Island pluton. The schist is interpreted as a metasedimentary rock on the basis of its composition. The schist contains rare 5mm polycrystalline quartz clasts, 3mm quartz eyes and trace tourmaline, kyanite and mirror feldspar. Although superficially similar to foliated schists derived from unit Agt, this unit is more compositionally heterogeneous and contains a number of thin, interlayered mafic schists. The schist is also distinguished from intrusive, intermediate volcanogenic units and Kivernikov geochemical signature (Wilkinson, unpubl. data), it may represent an altered equivalent of units Awvc and Awf.

Felsic to intermediate volcanic rocks (unit Awvf and Awwf) associated with iron-formation is present within bimodal mafic-felsic volcanic rocks southeast of Third Portage Lake and felsic-intermediate volcanic rocks on Horseshoe Peninsula. The mantle consists of alternating cm-scale beds of fine-grained quartz dolomite, coarse dolomite, and fine to medium-grained dolomite-calcite. The quartz-dolomite layers consist of a granular matrix of dolomite ± calcite and biotite with minor, rounded to subangular sand-size grains of quartz, and discrete 5mm grains of 50% quartz-50% dolomite ± calcite. Rare, thin (1-2 cm) beds of quartz-dolomite with 1-2 mm quartz eyes are also found. The contents tremolite, phlogopite, and rare humite, Zaleski et al., (2001) have interpreted the marble as a possible stromatolitic carbonate.

Clastic sedimentary rocks with minor quartz pebble conglomerate (unit Awsg) underlie the northeast part of the map area. These rocks are fine to medium-grained, wellbedded, chlorite ± biotite schists that are characterized by cm to dm scale beds grading upward from greywacke to mudstone, and that locally display flame structures. Although the schists are similar in composition to the volcaniclastic rocks, they are distinguished on the basis of their bedding and conglomerate beds within unit Awsc. It may represent a more distally deposited, equivalent facies of the volcaniclastic rocks.

Biotite and chlorite schist (unit Awsb) forms several thin (< 100 m) but continuous horizons within the reworked and primary volcanic rocks. These thinly bedded, 2-10 cm, fissile schists are bedded on a cm- to m-scale and are likely more extensive than depicted, as they weather poorly and are locally recessively.

Amarulik wacke and associated rocks

A distinctive package of schistic greywacke and related rocks, termed the Amarulik wackes (Zaleski et al., 1999a, b) occurs south of Third Portage Lake. The predominant unit is an arkosic greywacke consisting of ~ 3 mm quartz and feldspar crystal and lithic clasts in a coarse-grained bt-mus-qtz-fs matrix. The lithic clasts include quartzite, vein quartz, quartz-feldspar porphyry, and rare felsic volcanic rocks. Bedding is defined by 1-10 cm beds that are characterized by thick, cm- to m-scale, massive beds displaying only local grading, poor sorting, and more abundant feldspar crystal clasts. Oxide-facies iron-formation (unit Awfr) and pebble conglomerate (unit Awcg) are present as minor, interbedded units.

The pebble conglomerate contains unsorted, granule- to cobble-sized lithic clasts in a massive quartzite/psammitic matrix. It is oligo (quartz pebbles) to polymictic and bedded on a m-scale, containing clasts of (in decreasing order of abundance): quartzite, vein quartz, iron-formation, felsic volcanic rocks, and quartz-feldspar porphyry. Unit Awcg, as bolitic pebble beds, are interbedded with the thickest unit of iron-formation and underlie the eastern and western margins of the arkosic greywacke. Modified, cm-scale bedding is defined by varying proportions of biotite and concentrated layers containing contents, staurolite, andalusite, garnet, or amphibole.

Immediately south of the map area the Amarulik arkosic greywacke forms a major regional package that is interpreted to be mus, cb, Zf Sa-Pl Qtz-bt of Davis and Zaleski(bxl > 2.6 Ga (Roddick et al., 1992). In this area the Amarulik wackes also contain intermediate-mafic volcanic rocks not present in the Third Portage area, and are interpreted to be a reworked volcaniclastic deposit (Zaleski et al., 1999b). It is possible that it may be a facies equivalent of the 2.71 Ga volcanic succession.

Quartzite and associated rocks

The third major stratigraphic package of the Meadowbank map area consists largely of quartz-rich rocks; quartzites, quartz-pebble conglomerate, and minor, interbedded pelites and greywackes that are assigned to the Second Portage group. The quartzites themselves (unit Aflqz) are strongly recrystallized, massive to schistose, quartz arenites that locally contain heavy mineral layers with up to 7% magnetite-ilmenite-chromite, Primary beds (and rarely cross-beds) are defined by 1-10 cm variations in the proportion of quartz eyes and the proportion of biotite and muscovite. Muscovite is disseminated through the unit and defines bedding but increases to 20% where quartzite is strongly sheared, particularly along the unit contacts and throughout the isolated quartzite body immediately north of Third Portage Lake.

Quartzite occurs as two major associations: 10's km thick units with interbedded slate and phyllite (unit Aflsl), such as that exposed northwest of Third Portage Lake, and thinner, up to 2 km thick, laterally continuous units without interbedded pelite (unit Aflqz), such as that found on Third Island. The latter quartzites are commonly associated with pelites (Aflsl) and thin interval to rich associations, forming thin to thick (decimeters-hundreds) packages with underlying mafic flows (quartzite and slates (as at Sussex Lake), and in- to 100's m-scale units at the basal contact of the thin quartzite units. Unlike the Central BIF and along Tehek arm), The conglomerate consists of white quartzite and vein quartz clasts, with minor grey polycrystalline quartz and rare hydrothic clasts in a micaceous quartz-rich matrix. Bedding is defined by variations in the proportion of clast size.

Polymictic conglomerate associated with quartzite has been identified at several localities between quartzite and the volcanic sequence on the northwest shore of Second Portage Lake, and between quartzite and the West BIF on the north shore of Third Portage Lake. The conglomerate contains subrounded to rounded clasts of quartzite and other variations in water levels. The Second Portage conglomerate (unit Aflcg) contains pebbles, cobbles, and boulders up to 1m of (in decreasing order of abundance) white to buff quartzite and vein quartz, iron-formation, grey polycrystalline quartz, and rare hydrothic clasts in a micaceous quartz-rich matrix. Bedding is defined by variations in conglomerate, with which it can be bedded on a m- to 10's m-scale. The West BIF occurrence (unit Aclg) is dominated by quartzite pebbles, polycrystalline quartz and iron-formation clasts, and occurs at an apparent conformable contact between Archean quartzite and ultramafic rocks.

The association of polymictic and oligomictic conglomerate with thick quartzite units has been interpreted as evidence for a disconformity between the 2.71 Ga rocks and the younger quartzite and pelite (Zaleski et al., 1998a, 2000). The lower contact of the conglomerate infer a Tunnee lake and the large thick quartzite body to the north with is similarly interpreted to be unconformable. The relative stratigraphic position of the thinner quartzite units is presently unknown, as they are not associated with conglomerate. Detrital zircons from the Second Portage quartzite and pelite rocks are mixed. As recent U/Pb geochronology has established that a thick quartzite-slate sequence at Whitehills Lake to south is Proterozoic (Pehrsson et al., 2002), the thick quartzites and related map units are designated as Archean on this compilation, whereas those quartzites apparently interbedded with the Archean volcanic rocks are interpreted as Archean.

PLUTONIC ROCKS

Plutonic rocks of both Archean and Paleoproterozoic age are interpreted to be present in the Meadowbank map area. The oldest unit associated with the plutonic rocks is the Tern Lake porphyry (unit Alp), a layered, quartz and K-feldspar-phyric porphyry dated at ca. 2.83 Ga (Davis and Zaleski, unpubl. data), situated just south of Tern Lake, The unit is characterized by 2-5 mm, euhedral quartz and K-feldspar phenocrysts in a fine- to medium-grained, quartzofeldspathic textured and lesser plagioclase phenocrysts in a fine- to medium-grained, quartzofeldspathic matrix. Minor biotite and ratio hornblende phenocrysts (to 2 mm) have been noted and ilmenite, chalcopyrite, pyrite, and magnetite are present in trace amounts.

The Tern Lake porphyry is variably sheared, typically more highly sheared on its margins, and shows considerable textural and grain size variation along strike, At its southwestern end it is a strongly layered, "cyflaceous" looking rock with 1-2 mm, 1-5% qtz and fs eyes in a fine grained, qtz-fs matrix. It is massive to layered in the middle of the northeastern end it is a well foliated to locally mylonitic, K-feldspar and plagioclase porphyritic (5-15 mm), biotite-hornblende granodiorite (unit Alpg) with up to 15% desseminated sulphides. Fine-grained porphyry can be interfingered at the 10's m-scale with coarser-grained granite, Based on the overall texture and association with coarser-grained granitic rocks, the Tern Lake porphyry likely represents a deformed high-level, locally extrusive, equivalent of unit Alpg.

Systematic mapping was not conducted in the large granitoid domains that underlie the eastern and western margins of the map area, consequently only an overview of these rocks is given here. Preliminary examination suggests that the granitoid rocks can be divided into two broad groups, based on age, texture, and composition, where possible, The predominant map unit is a pink, megacrystalic to K-feldspar megacrystic (1-2 cm) monzogranite to granite (unit Agt) with biotite and/or hornblende, epidote, and magnetite in a variably recrystallized groundmass. In thin section, the rocks are typically hypidiomorphic granular, with 1-2 cm microcline crystals in a fine- to medium-grained, Pl-Kfs-Qtz matrix phases, although these can be highly chloritized, It is commonly well foliated, with foliation defined by alignment of megacrysts, quartz grain-shapes, and mafic minerals, The margin of the western domain is characterized by a 1-2 km wide zone of migmatitic rocks, Where observed, the migmatites are commonly found in 1-2 m wide, highly sheared intrusions in adjacent country rocks, The eastern domain is less strained overall along its margin, although highly deformed granite sheets are also present along its contact zone. A composite U-Pb age of 2612 ± 4 Ma (Roddick et al., 1992) has been obtained from both domains.

Minor granites to syenitic stocks and dykes of suspected Paleoproterozoic age (units Pmgr, Pmgr) are found throughout the map area. They are 1-10 m wide, 10's m long, and typically trend northeast and dip steeply to the east and west respectively, The felsic granites (unit Pmgr) are coarse-grained, dark red, leucocratic and are vuggy textured locally, and have similar composition, accessory mineralogy, and geochemistry as the 1.76 Ga felsite granite suite (Petersen et al., 1993). The more mafic intrusions (unit Pmgr) are fine- to medium-grained, grey to green, and similar to the 1.87 Ga Pipe dyke, may be a related body, Similar small stocks, also interpreted as felsite granites, are found just northwest of the map area at Pipedream Lake (Zaleski et al., 1997). A small body of leucocratic, inequigranular, biotite-garnet granite is found on the northeastern shore of Second Portage Lake. It is texturally and compositionally similar to the ca. 1,835 Ga Paleoproterozoic Hudson granites (Petersen et al., in press), a suite that occurs as abundant dykes immediately south of the map area, and as large plutons further south towards Baker Lake.

Late crosscutting lamprophyre dykes, interpreted to be related to minette flows of the Baker Lake group (Rainbird et al., 2001), are observed in drill core (Sherlock et al., 2001a, b) and are reported to occur in outcrop (Armitage, 1992), but were not observed during the present mapping.

Mafic to felsic intrusions of unknown age form two distinct suites in the map area, Gabbro, quartz leucogabbro and monzodiorite (unit Agb) form small stocks southwest and east of Tern Lake and a larger composite body south of Third Portage Lake. They are fine- to medium-grained, massive to foliated and lineated and are similar to rocks of the Woodburn group, These bodies are associated with localized magnetic anomalies, a wild spirillic texture and geochemistry distinct from unit Awa, Northeast of Pipedream Lake, a gabbro body of similar geochemistry and magnetic signature to unit Agb is interpreted to be a synvolcanic sill related to the mafic volcanic sequence.

Biotite-muscovite granite is present in the map area as dykes and sheets and several minor stocks that intrude the volcanic sequence (unit Agmp). These leucocratic, inequigranular to weakly K-feldspar porphyritic intrusions are characterized by 5-7% biotite and lesser muscovite in a foliated to locally mylonitic, recrystallized groundmass, They are not observed to cut the other intrusive rocks, consequently their relative age is uncertain.

STRUCTURE

Four phases of ductile deformation affect all rocks of the Woodburn group in the Meadowbank deposit area, and are correlated with structures identified regionally (Pehrsson et al., 2000). The sequence elaborated here builds on that established by Henderson et al., (1991) and Ashton (1988),

D_1 is represented by bedding-parallel foliation, and thin sectionscale axial-plane foliation, and thin sectionscale axial-plane foliation for two sets of pre-D_2 isoclinal folds and foliations that are found only within the 2.7 Ga Woodburn group volcanic and related rocks, These local observations and the significantly greater intensity of overall strain in this sequence suggest that the 2.7 Ga volcanic rocks were likely deformed prior to deposition of the thick quartzite sequence.

The earliest regional deformation event, D_2, involved development of macroscopic, shallowly-plunging, isoclinal F_2 folds, S_2 axial planar foliations, and L_2 mineral lineations. Bedding-parallel shear zones are also related to this event. F_2 folds of bedding and quartz veins, is defined by (shallow)dip and chlorite alignment and quartz grain shape fabrics in the supracrustal rocks, and phenocryst elongation and mineral shape fabrics in all plutonic rocks with the exception of unit Agt. S_2 is the dominant fabric in the supracrustal rocks, and is axial planar to F_2 folds of bedding and quartz veins, measurable F_2 folds and variably overprinted by S_3, making delineation difficult in the field). The timing of D_2 is bracketed by intrusion of the 2,539-2,620 Ga granite suite and 1,835 Ga, the age of a post-D_2 pegmatite dyke (Roddick et al., 1992). Evidence for pre-D_2 deformation is observed in drill core at the Goose Island deposit (Ma et al., 1999; Davis and Zaleski, 1999) most likely reflects regional strain heterogeneity, If D_1 schistosity in the ca. 2.7 Ga Whitehills conglomerate (Davis and Zaleski, unpubl. data) is correlative with S_1 of the deposit area the regional D_1 deformation event is bracketed between 2.7 and 2.6 Ga.

F_2 folds at all scales are shallowly doubly-plunging folds of S_1, North and west of Third Portage Lake they form a map-scale northeast-vergent fold set with moderately southeast-dipping axial surfaces (Fig. 4a). South of Third Portage Lake, F_2 folds are tight to isoclinal, moderately to steeply dipping, and verge to the northwest. To the west, North and east of Second Portage Lake F_2 axial surfaces and S_2 have variable orientations due to superposed F_3 folds (Fig. 4b,c). The regional northwest-vergent F_2 fold/fault belt deforms the Archean granites, and is therefore the result of Paleoproterozoic deformation (Fig. 4d).

A major NW-vergent D_3 thrust fault places 2.71 Ga Woodburn group volcanic rocks on the unconformably overlying quartzite sequence north of Third Portage Lake, This structure may link with a zone of D_3 high strain that extends through the deposit area and south through Second Portage Lake (Fig. 4d). This zone is characterized by increased tightness of F_2 folds, strong S_2/S_3 transposition fabrics and local mylonites, and has been termed the Third Portage shear zone (Zaleski et al., 1998a, 2000; Sherlock et al., 2001a, b). The thrust fault at the Goose Island contact at Camp Island and extends south of Third Portage Lake where a F_2 isoclinal fold of iron-formation is apparently truncated against its trace, suggesting the zone may be the locus of significant dislocation, and possibly a thrust fault.

D_4 structures consist of open to close F_4 folds of S_2/S_3, with an associated L_4 crenulation lineation, F_4 chevron to similar-style folds of S_2 and L_2 have wavelengths on the order of decimeters to centimetres, The shallowly plunging to subhorizontal L_4 lineation is defined by the intersection of S_4 crenulation cleavage with S_2 and S_3 and by crenulations on crenulate surfaces such as grunerite that are randomly oriented on S_2, F_4 folds define a consistently southeastverging minor fold set with shallowly north- and northwest-dipping (~ 40°) axial surfaces, These folds locally overprint F_3 folds and are found in the Second Portage Lake area and in the Whitehills Lake area, 15 kilometers, defined by crenulations of S_3 and rare growth of muscovite in chlorite, are typically only visible in thin section.

Mapping east of Whitehills Lake (Zaleski et al., 2000) indicates that D_4 structures overprint a suite of synmonzodiorite intrusions that are correlated, on the basis of composition and geochronology, with dated, ca. 1835 Ma intrusions at MacQuoid Lake (Davis, unpublished data). This suggests that D_4 deformation postdates ca. 1840 Ma. A similar relationship is observed at the Tehek Lake area (see also Zaleski et al., 2000), where F_4 folds of S_3 and the Tehek Lake porphyry/diabase dyke swarm (Fig. 1). The Tehek Lake porphyry has been dated at 1784 ± 2 Ma (Wilkinson et al., 1999) and the dyke swarm is correlated with the Mackenzie dyke swarm (Lecheminant, pers. comm.), however this type of deformation is unknown in the Baker Lake Group (Fig. 2).

METAMORPHISM

The map area preserves evidence of three distinct metamorphic events, designated M1 to M3, M1 regional metamorphism is observed in the Archean supracrustal rocks and granitoid rocks, M1 is characterized by the unknown pressure and is constrained to prebke development of D_2 structures ca. 1.9-1.8 Ga and post-dates the 2.83 Ga granites that carry S_2 foliations (Fig. 2). As is the case with D_2, M1 may post-date deposition of the Paleoproterozoic Whitehills conglomerate if regional correlation of fabrics is established.

M2 regional metamorphism is characterized by mid-greenschist through amphibolite facies assemblages developed in rocks of appropriate composition, Peak metamorphism is observed in the Tehek Lake area (Tehek circuit), data, Greenschist zone M2 phases such as chlorite-bt, kyanite, chlorite, and biotite are typically aligned in or wrapped by S_2, whereas amphibolite zone porphyroblasts, including staurolite, andalusite and garnet, both overgrow and wrap S_2 fabrics, Peak metamorphic assemblages in pelitic rocks are typically bt-ms-qtz-pl, although staurolite-bearing inclusion trails smoothly continuous with matrix S_2, This is evidence and recrystallization of D_2 phyllosilicates that are crenulated by S_2 suggest that M2 regional metamorphism was broadly coeval with D_2 but that the thermal peak outlasted deformation.

Distribution of characteristic mineral assemblages defines three metamorphic mineral zones: mid-greenschist, upper greenschist or epidote amphibolite, and amphibolite (Fig. 5), The mid-upper-greenschist zone boundary trends northwest from Tunnel Lake, across Third Portage Lake and east-northeast just north of the Third Portage deposit, The upper-greenschist/amphibolite zone boundary trends roughly east-west across Third Portage Lake, passing just south of the Goose Island deposit, Peak metamorphic conditions in the mid-greenschist zone are estimated from the transition-corrosion P-T conditions of the M2 metamorphic zone to ca. 450°C at 4 kb, 5.5 kbars. Assemblages of the upper-greenschist zone collectively suggest temperatures of ca. 450°C at low pressures, The occurrence of the assemblage staurolite + andalusite + bt + ms + qtz + pl in the Tehek Lake area (see also Zaleski et al., 2000) suggests thermal-chemical conditions data (Miller, unpub., report) yield amphibole zone conditions of 2.0 kbar at ca. 540°C, for Goose Island, just south of the zone boundary, Local fo2b- y ti assemblages in ultramafic rocks and the maximum stability of the assemblage chlorite + tremolite + talc + magnesite in metabasalt (Spear, 1993) suggest that the mid-upper greenschist phyllogite marble suggests M2 temperatures locally above 600-650°C, The trace of the upper-greenschist and amphibolite zone boundaries crosscut D_2 structural trends, possibly due to post-thickening thermal relaxation.

Retrograde M3 metamorphism is observed in the Archean supracrustal rocks and granitoid rocks, M3 is not bracketed by D_2 fabrics, but are wrapped and/or crenulated by S_3, These phases, characteristically prograde (pl, bt and cum) are, patchily distributed across the mid-upper greenschist and amphibolite zone boundaries (Fig. 5), South of Third Portage Lake, distinct late chlorite and muscovite fabrics and similarly crenulated by S_3, Pressure-temperature estimates of ca. 450°C at 3.0 kbar have been obtained from M3 gruneh and gibbsite assemblages in drill core from the Goose Island deposit (Ma et al., 1999; Davis and Zaleski, unpubl. data), and from Ashton et al., 1989) ages of M3 biotite porphyroblasts in the deposit area are 1,722 and 1,791 ± 30 Ma, respectively, indicating the time of cooling through the 300°C isotherm, It is possible that M3 metamorphism represents a local, thermal event effect related to fluid/re-fluids metamorphism.

ECONOMIC GEOLOGY

The Meadowbank gold deposit comprises four deposit zones localised within and adjacent to iron-formation of the Central BIF (Fig. 4d). Gold occurs in iron-formation at its contact with komatiite or ultramafic sediments and only in rare instances within the komatiite, Gold mineralization is associated with pyrite ± arsenopyrite and is typically restricted entirely to within the Amarulik wackes are conservative to fluxes, The deposits are controlled in the mode and along the limbs of D_2 and D_3 isoclinal folds, and show multiple styles of sulfide mineralization (Pehrsson et al., 2000; Sherlock et al., 2000a, b), associated to varying degrees with pyrrhotite-gold concentrations, Pyrite styles are grouped according to their relationship to the major deformation phases, pre-D_2, D_2, and post-D_2 (Sherlock et al., 2000a, b), Pre-D_2 pyrite is fine-grained, disseminated, and is found in the ultramafic rocks, iron-formation, pelite, greywacke and variable gold concentrated within D_2 and D_3 foliations, with or without magnetite, These sulphides are found within or adjacent to quartz veins deformed in S_2 or S_3 foliations and veins that cut S_2 but are deformed by D_3 structures, The D_2 veins are commonly boudinaged and folded, and contain pyrite, pyrrhotite, and gold in variable patterns at mm-section scale and are localised along shears parallel to S_2, Regional evidence for pre D_2 mineralization comes from disseminated pyrrhotite and chalcopyrite in units Awmv, Awfv and Awf that display grain size, and consider that this thick upper sequence could be Proterozoic in age, similar to the dated sequence at Whitehills Lake, Repetition of the quartzite as thinner units within the volcanic package and underlying the Amarulik wackes may be the result of D_2 isoclinal folding, Alternatively, the thinner quartzite units may be correlative with the Second Portage group, Van Breemen et al., 1981), although the Whitehills dated (Pehrsson et al., 2002) and the Tehek stratigraphic package itself, an interpretation supported by Sherlock et al., (2000a, b), The Amarulik wackes themselves have previously been interpreted as volcanogenic rocks derived from and in part contemporaneous with the 2.71 volcanic sequence (Henderson and Henderson, 1994), Resolution of these stratigraphic questions awaits further investigation.

Mineralization

Several models have been proposed for the genesis of the Meadowbank gold deposit, Miller (1997) emphasized the syngenetic nature of the sulphides for the Goose Island deposit, Armitage et al., (1996) suggested that gold mineralization was syn- to post-the 2,6 Ga granites and related to sulphidation-alteration reactions concentrated in the Central BIF, Zaleski et al., (1998a) suggested that gold was introduced during the 2.68 Ga volcanic event, Sherlock et al., (2001a, b) elaborated on this model, linking mineralization and alteration to progressive D_2-D_3 deformation and localization of strain adjacent to the Central BIF stratamorphic-iron-formation contact.

Gold mineralization is hosted by the Amarulik wackes, which have been dated at ca. 2,6-1,8 Ga in age, consistent with the general models of Armitage and Sherlock, Given the evidence for high-strain zones along the West BIF-komatiite/quartzite contact, additional influences are required to explain the localisation of economic mineralization in the Central BIF.

Interpretation of the distribution of lithologies in the map area shows that unit Awmv is spatially associated with the auriferous Central BIF and the Dogleg Lake synvolcanic porphyry (unit Awf), dated at ca. 2,7 Ga (Davis and Sherlock, unpublished data), Geochemical and textural evidence suggests that unit Awmv is a sericite and chlorite altered rock of volcaniclastic unit Awvc protolith that was altered prior to D_2 deformation, Given this association and the local spatial association of gold mineralization with the Dogleg Lake synvolcanic porphyry, it is suggested that the present day distinct mineralogy of the Central BIF and distribution of the unit Awmv schist may in part reflect synvolcanic and regional alteration adjacent to 2,7 Ga porphyry, This alteration may have acted as a ground preparation event, making the Central BIF a preferential site for syn-D_2 mineralization over the West or East BIFs.

ACKNOWLEDGEMENTS

Cumberland Resources Ltd. is gratefully acknowledged for logistical support of the project, access to drill core samples and airborne geophysical data, Mike Thomas is thanked for producing vertical derivative magnetic maps, Ashton Mining of Canada provided helicopter support, Discussions with Jean Armitage, Bill Davis, John Kerswill, Rob Berman, and Hamish Sanderman are thanked for stimulating discussions.
