GEOLOGICAL SURVEY OF CANADA | COMMISSION GÉOLOGIQUE DU CANADA

DESCRIPTIVE NOTES

INTRODUCTION

This 1:100 000 scale map and the accompanying Open File 1794 maplinset 2 (NTS 56 P (North)) present results of bedrock mapping in the Ellice Hills area, Nunavut, undertaken by the Geological Survey of Canada (GSC) as part of the Targeted Geoscience Initiative (TGI) during the summer of 2002. The objectives of the project were to upgrade the geological knowledge of the area, to investigate the nature of the Walker Lake intrusive complex and to provide geological maps for the region. The Ellice Hills map area (NTS 56 P) is underlain by northeast-trending rocks of the Rae Province (Fig. 1, Table 1, sheet 2) and the Paleoproterozoic Hudson Orogen (Fig. 1, Table 1, sheet 3) and is the association of quartzite and komatiite, Previous investigations of the Committee Bay belt (Fig. 1,2), include reconnaissance mapping (1:506 880) of Heywood (1962) and the subsequent 1:250 000 scale mapping in parts of the Committee Bay belt by Schau (1980) and Schau and Henderson (1983). In addition, the Ellice Hills area encompasses a new national park at Wager Bay (Fig. 1), including the headwaters of the Brown River, but to a minimal resource assessments by the Geological Survey of Canada (Jefferson and Schau, 1982; Chandler et al., 1993). As a result of the GSC's recent mapping in the Committee Bay belt, a number of publications and digital products at various scales are available (eg., TGI Laughland Lake (56 K, Sanderson et al., 2001a), Jeremejeva (2002), Johnstone et al., 2002, Kivi et al., 2002, Sanderson et al., 2002, Sanderson et al., 2003, Sanderson et al., 2004, Skulski et al., 2002, Skulski et al., 2003a, and 5 Ellice Hills (56 P, this map; Sanborn-Barrie et al., 2003, Skulski et al., 2003b). Geological mapping in the Committee Bay belt by Kivi et al. (2002), Kivi and Skulski (2002), Skulski and Kivi (2003), and Kivi and Skulski, (2003), are the results of surface mapping and drill prospecting (Little, 2001; Little et al., 2002; McMartin et al., 2002, 2003; Copp and Hiatock, 2002; Lilling et al., 2002; Sopuppat et al., 2003), an investigation of the Walker Lake intrusive complex (Fig. 1, Table 1, sheet 2) and the Paleoproterozoic Hudson Orogen (Fig. 1, Table 1, sheet 3) which is also a gold-bearing belt of rocks with a mean terrain clearance of 150 m (Kivi et al., 2002; Sanborn-Barrie et al., 2003). These datasets have been integral in the production of this map, particularly in regions of extensive Quaternary drift.

REGIONAL GEOLOGICAL SETTING

The Committee Bay area, in the central part of the Churchill Province, lying west of Hudson Bay, contains a discontinuous, ca. 1800 km long, northeast-trending belt of supracrustal and metamorphosed Archean supracrustal belts with a diagnostic quartzite komatiite association, that includes the Woodburn and the Prince Albert groups (Fig. 1). The supracrustal belts are flanked by, and in part infolded with, granitoid rocks of the Rae Province (Archean crustal and older rocks basement (e.g., Taff Dy Dalton et al., 2001) and the presence of older Rae or Hearne-like basement (Hearne Province) is suggested by the presence of ca. 2.9 Ga detrital zircons in the Prince Albert Group (Kivi et al., 2002). Within the northeast-trending corridor include komatiite, basalt, andesite, dacite, and rhyolite, the latter two yielding U-Pb zircon ages of 2.72 Ga (Kivi et al., 2002) and 2.71 Ga (Kivi et al., 2002; Kivi and Skulski, 2002; Kivi et al., 2003a, 2003b and references therein; Skulski et al., unpublished). Archean plutonic rocks in the region appear to be dominated by calc-alkaline granitoid plutons emplaced between ca. 2.81 and 2.58 Ga (Ashton, 1998; LeCheminant et al., 1987; Peterson et al., 2002; Kivi et al., 2003a; Sanborn-Barrie et al., unpublished).

Sutters, a variably dipping of geothermal to basinal facies. Paleoproterozoic metasedimentary rocks are found throughout the region (Fig. 1). These include the: 1.87-Ga Amer Group (Tella, 1994); the ca. 1.85-Ga Penrhyn Group (Jackson and Taylor, 1972); the ca. 1.84-Ga Piling Group (Aspler et al., 2001; Aspler and Chiarenzelli, 2002). In the Committee Bay area, small outliers of Paleoproterozoic metasedimentary rocks include: 1.83-Ga quartzite in the Walker Lake area (Kivi et al., 2002; Kivi and Skulski, 2002; Kivi et al., 2003a, 2003b); and 1.84-Ga quartzite in the central Ellice Hills (Skulski et al., unpublished; Table 3). These Paleoproterozoic sedimentary sequences have sustained only low-grade metamorphism and are relatively undeformed (Fig. 2).

Archean and Paleoproterozoic strata in the region have a prominent northeast-striking tectonic fabric that is concentrated in the Committee Bay and Woodburn Lake areas to have formed between ca. 1.87 and 1.82 Ga (Zaleski et al., 1999; Kivi et al., 2002; Kivi et al., 2003a, 2003b; Sanborn-Barrie et al., 2003; Skulski et al., 2003a, 2003b; Regnault, 2003), deformation in the form/stem of the Trans-Hudson orogen. Dy shown is generally superimposed on earlier D₁ fabrics and folds that formed after 2.6 Ga, but before 1.85 Ga (Fig. 2; Carson et al., 2003; Sanborn-Barrie et al., 2003). Deformation in the Committee Bay area is concentrated in a northeast-trending corridor, which is ~100 km wide (subparallel), west-striking shear zones in the region oriented D₂ fabrics and include the Prince Albert, Walker Lake, Laughland Lake, Arrowsmith River and Northern Migmatite subdomain shear zones.

In the Committee Bay area, Paleoproterozoic intrusive rocks include late- to post-tectonic ca. 1.82 Ga calc-alkaline granitoid plutons (Kivi et al., 2002; Sanborn-Barrie et al., 2003; Skulski et al., 2003a, 2003b; Sanborn-Barrie et al., unpublished) and komatiite-tholeiite dikes (Kivi et al., 2003a,b). Proterozoic units equivalent to the ca. 750 Ma Nueltin Suite (Peterson et al., 2002) have not been documented in this part of the Rae domain; however, a small occurrence of ca. 1.27 Ga gabbro-diorite has been identified in the Ellice Hills area (Kivi et al., 2003a) and may be referred to be correlative with the Nueltin Suite. The northeast-trending, ca. 1,267 Ga gabbroic Mackenzie dykes cut all Archean and Proterozoic rocks.

GEOLOGY OF THE COMMITTEE BAY AREA

The Committee Bay area is generally underlain by three, lithologically distinct, northeast-trending crustal domains (Sanborn-Barrie et al., 2003; Fig. 1). The Rae domain, in the northwest part of the area, is characterized by granitoid rocks with subordinate paragneiss and supracrustal rocks (Fig. 1). The central Committee Bay belt is a northeast-trending belt of supracrustal rocks belonging to the Prince Albert group (unit Pag), herein collectively called the Committee Bay belt (Sanborn-Barrie et al., 2003). The Committee Bay belt is bounded to the northwest by the Walker Lake shear zone. Metasedimentary and volcanic rocks of the Committee Bay supracrustal belt (Fig. 2) in the NTS 56 P map sheet are mainly exposed in the southern part of the mapsheet, although thin, discontinuous rafts, lenses, and xenoliths occur throughout the map area (Fig. 3; Sanborn-Barrie et al., 2003). The Committee Bay belt is dominated by metasedimentary paragneiss and quartz arenite; less common rocks in the region are banded iron formation and ultramafic rocks and volcanogenic rocks, including basalt, andesite, dacite, and rhyolite (Fig. 2). The Committee Bay belt is bounded to the southeast by medium-grained, variably foliated ean to post-tectonic granites that intrudes the supracrustal rocks, and to the northwest by a belt of variably foliated to gneissic, equigranular, and monzodiorite-porphyritic to, 2.81 Ga granodiorite and monzogranite.

The southern domain is underlain by the regionally extensive, potassic, Walker Lake intrusive complex, which is dominated by monzogranite and granodiorite (Fig. 1). Rocks of the Committee Bay belt in the Ellice Hills area, in the northern domain is difficult to determine in the map area. Much of the area lying immediately North of the Committee Bay supracrustal belt is underlain by voluminous, homogenous, moderately foliated, and foliated potassium-feldspar megacrystic granite (unit Awl) and pegmatite (unit Apt). Rocks of the Committee Bay belt, in the Ellice Hills area, are supracrustal units, is widely intruded by a range of younger, variably foliated granodiorite through monzogranite, biotite ± hornblende ± titanite ± magnetite monzogranite to granodiorite (unit Agn). Rocks of the Committee Bay belt, in the ca. 750 Ma Nueltin Suite (Peterson et al., 2002) have not been documented in this part of the Rae domain; however, a small occurrence of ca. 1.27 Ga gabbro-diorite has been identified in the Ellice Hills area (Kivi et al., 2003a) and may be referred to be correlative with the Nueltin Suite. The northeast-trending, ca. 1,267 Ga gabbroic Mackenzie dykes cut all lithological units and structures.

GEOLOGY OF THE ELLICE HILLS AREA (56 P)

SUPRACRUSTAL ROCKS OF THE PRINCE ALBERT GROUP (Pag)

Amphibolite and mafic volcanic rocks (unit Aav)

On the basis of preliminary U/Pb geochronology and stratigraphic relationships, basaltic rocks appear to form the oldest part of the Prince Albert Group (Pag) in the Ellice Hills area. Basaltic rocks underlie a relatively large part of the map area (Ellice Hills belt) and basaltic rocks are also found in a number of smaller, fault-bounded inliers. Underlain by knobby and irregular surfaces resulting from preferential weathering of amentia and cattle. The mafic rocks are commonly massive, but locally display a weak to moderately foliated fabric. Basaltic rocks are commonly dark green to black and aphanitic to fine-grained, porphyritic. Primary volcanic features such as pillows, lava shelves, or amygdaloid have been observed at very few localities in the western, lower-grade part of the belt but were rarely recognized in the 56 P map area (Fig. 3, sheet 6).

Intermediate volcanic rocks (unit Aiv)

Intermediate volcanic rocks are rare and typically occur as laminated hornfelsed rocks that are interlayered with sedimentary or paramictite (unit Apg, basalt (unit Aav) and ultramafic rocks (unit Auv) southwest of Kringalugaaq Mountain (Fig. 2). Primary volcanic features were not identified.

Komatiite (unit Auv)

Ultramafic rocks are typically the most abundant rocksin?) igneous rocks comprising the Pag. They commonly form thick (300 m), prominent ridges relative to the surrounding metasedimentary units. These rocks comprise thin, discontinuous, lenses, rafts, and xenoliths within the Committee Bay belt and are commonly found in close proximity to the basal contact of the Committee Bay belt with the underlying basaltic rocks (unit Aav). Ultramafic rocks are commonly found in close proximity to the basal contact of the Committee Bay belt with the underlying basaltic rocks (unit Aav). Ultramafic rocks are commonly found in close proximity to the basal contact of the Committee Bay belt with the underlying basaltic rocks (unit Aav) southwest of Kringalugaaq Mountain (Fig. 2). These units locally exhibit schistose, talc-serpentine or talc-anthophyllite margins.

Iron-Formation (unit Ai)

Iron-formation occurs locally throughout the Pag as discontinuous, < 30 m wide units, and includes: finely laminated magnetite-and chert bands (Fig. 3); centimeter to decimetre scale layered garnet-amphibole-rich layers (chloritic alteration?) (Fig. 3); and massive, boudinaged, and folded magnetite units. Iron-formation is commonly found in subtidal minerals, iron-formation commonly occurs as interlayered combinations of the aforementioned types and locally as iron-rich clastic schists. Subphides, mostly pyrrhotite and pyrite with minor arsenopyrite and chalcopyrite (Fig. 3), are commonly associated with iron-formation. Iron-formation is commonly found in close proximity to, and within weathering structures (unit Aav) southwest of Kringalugaaq Mountain (Fig. 2).

Quartz arenite (unit Aqz)

Quartz arenites are common in the southern, Committee Bay supracrustal belt, and form prominent hills in the southwest and central parts of the map sheet. These comprise muscovitic, white to gray, decimetre scale bedded quartzites and quartz arenites. Sedimentary structures include: trough cross-bedding, ripple cross-lamination, tabular and magnetite iron-formation, and phyllosilicate horizons. Collectively, the quartz arenite units form laterally continuous marker horizons that locally exhibit primary structures (grading, scour) indicating stratigraphic younging. Quartz arenites are commonly found in close proximity to the basal contact of the Committee Bay belt and are interpreted by Schau (1980) as accumulations of detrital from paleoweathering of adjacent ultramafic and felsic rocks. In the Kringalugaaq mountain and the Curtis River areas, quartz arenite commonly contains orange-weathering, pyrrhotite-rich garnet ± biotite ± cordierite-bearing metasedimentary rocks. These metasediments are commonly recrystallized, defining S_2 fabric.

Pflg (undivided- unit Apg)

The most abundant rock-types of the Pflg comprise lime-pyroxenite, biotite ± garnet psammite and semipelite that are interbedded on mm to dm-scale (Fig. 1 sheet 2). These rocks occur throughout the Pflg, generally form recessive, low relief outcrops and are commonly found in close proximity to the basal contact of the Committee Bay belt with the basaltic rock (gene, and local mussorite. They occur interbedded (< 30 cm) with rare pelitic, semitic, psaffitic, and quartz arenite units. Sedimentary structures include: trough cross-bedding, ripple cross-lamination, tabular and pebble lags, graded beds and crossbeds. Conglomerates were not observed in the 56 P map area. A specimen of pebble conglomerate from the Committee Bay belt, collected in the Curtis River area (Fig. 1, sheet 2), yielded a U-Pb zircon maximum age of ca. 2,697 Ga (Table 1, sheet 2) indicating that the northern belts of Pflf may be part of the upper Prince Albert group (Skulski et al., 2003b).

PLUTONIC UNITS

Peridotite sills (unit Apr)

A second variety of ultramafic rock that occurs throughout the Committee Bay belt in 56 P consists of layer-parallel, < 50m thick bodies of orthopyroxene-porphyritic and diorcpyric peridotite (Fig. 6). These generally do not show internal layering and are commonly massive, but locally display a weak, foliation-parallel alignment of primary mafic orthopyroxene that may be corrongruphic with the enclosing foliation.

Diorite and gabbro (unit Ad)

Mafic to intermediate plutonic rocks occur throughout the Pag area and comprise weakly to moderately foliated, medium-grained, commonly plagioclase porphyritic diorite, quartz diorite and rare gabbro, intruded by foliated and unfoliated granite (unit Agn) and pegmatite (unit Apt). Rocks of the Ad unit are commonly found as small, irregular intrusions of less to medium-grained, reddened biotite ± titanite ± magnetite monzogranite, and less commonly as dikes. The gabbros and diorites typically form discontinuous rafts and xenoliths in younger granite and pegmatite.

Tonalite (unit At)

Tonalite is relatively common throughout the map area and typically occur in close proximity to the supracrustal belts. These comprise moderately foliated and foliated, gray to pink, generally medium-grained biotite ± hornblende ± magnetite tonalite (Fig. 10). Tonalitic rocks typically contain subrounded schlieren, inclusions and rafts of diorite or gabbro. Tonalite is commonly found as small, irregular intrusions of less to medium-grained, reddened biotite (unit Agn) and, where these are highly sheared, a gneissic texture is locally developed. Tonalite is cut by all of the other plutonic rocks in the map area. Tonalite is commonly found in close proximity to the basal contact of the Committee Bay belt with the underlying basaltic rocks are generally post-volcanic at 2.81 Ga, but may also be synvolcanic at 2.72 Ga (Sutter, unpublished data).

Central granodiorite (unit Agn)

The dominant rock-type in the map area is variably foliated and foliated, grey to pink, medium-grained, biotite ± hornblende ± titanite ± magnetite monzogranite to granodiorite (Fig. 7). This unit dominates the central and northern parts of the map area north of the Committee Bay supracrustal belt. Megacrystic rafts and xenoliths of granodiorite, tonalite, and diorite are commonly found within the monzogranite and are found throughout. The granodiorite is cut by younger biotite ± magnetite monzogranite unit Agg, biotite ± hornblende granite (unit Ang) and potassium feldspar-megacrystic biotite ± magnetite monzogranite to granodiorite (unit Agg).

Potassium feldspar megacrystic monzogranite (unit Awg)

North of the Committee Bay supracrustal belt and, in particular, north of the Aimoyak fault an several elobe plutonic masses of biotite ± magnetite potassium feldspar-megacrystic granodiorite to monzogranite (Fig. 1), sheet 2). These are commonly massive, but locally display a weak, magmatic foliation. The monzogranite is commonly moderately developed foliation. The age of this unit is not well-defined, but it may represent a textural variant of unit Agg (see below).

Monzogranite (unit Ag)

Throughout the central and northern parts of the map area, particularly north of the Committee Bay Supracrustal belt, are several, < 1 km wide, irregular bodies of foliated and unfoliated, pink to grey, fine- to medium-grained, biotite ± hornblende ± magnetite monzogranite (Fig. 7). These are commonly found in close proximity to the more megacrystic granodiorite phases, types and sills in most other rock types and is commonly accompanied by outcrowing of the adjacent host rocks.

Pseudomorus granites (unit Ang)

Unlike the two map sheets to the southwest (Sanderson et al., 2001c; Skulski et al., 2003b), the Ellice Hills map area does not contain any large, homogeneous, post-tectonic granite plutons. Instead, the majority of the granitoid rocks in the western part of the belt where migmatite is exposed in the southern 56-O (Carson et al., 2003) and in the Aulgaq Lake area (Sanborn-Barrie et al., 2003). Granitoid rocks in the migmatite subdomain are commonly foliated and their intrusions are cut by large plutonic masses of variably foliated, biotite ± muscovite ± garnet-bearing, commonly 4-mica granite and pegmatite (unit Apt; Sanborn-Barrie et al., 2003). Granitoid rocks in the migmatite subdomain are commonly products from base migmatitic domains. These pandemonious plutons carry a weakly to moderately developed, undulating foliation, in contrast with well foliated adjacent tonalitic and granodioritic units. A U/Pb SHRIMP geochronological study of high-grade gneisses flanking the Committee Bay granite-gneiss terrain: implications for the Archean-Proterozoic boundary on Committee Bay, central Churchill Province, Nunavut, Canada (Sanborn-Barrie et al., 2004) yielded an age of ca. 2,677 Ga, suggesting the pandemonious granitoids may represent syn-to late-D₂ intrusions.

Walker Lake Intrusive Complex (unit AwLx)

Lying south of and intruding the Committee Bay supracrustal belt is the regionally extensive Walker Lake intrusive complex. The Walker Lake intrusive complex is dominated by medium-grained, variably foliated, pink to grey, biotite ± titanite ± magnetite monzogranite to granodiorite (Fig. 1). The latter unit is the dominant rock-type in the southern parts of the map area. Megacrystic granodiorite and monzogranite phases are commonly found in close proximity to the Walker Lake shear zone (Fig. 1, sheet 2
