

**High Sensitivity Airborne Gamma-Ray Spectrometric and Anomagnetic Surveys
Central British Columbia, 2004 - 2005**

In 2004 and 2005, Fugro Airborne Surveys completed two multi-sensor airborne geophysical surveys in the corner region of British Columbia for the Geological Survey of Canada, the British Columbia and Yukon Chambers of Mines, Vancouver First Nation, and two industry partners, including Sengstacke Resources Inc., Northern Minerals Ltd., Portland Ventures Corp., 2004 Resources Inc., and Arrium Resources Ltd. The Geological Survey of Canada provided survey supervision, and quality control. The results of the surveys were a series of geophysical maps, including gamma-ray spectrometric data. The surveys were flown over two seasons, from September 18 to November 17, 2004 and June 15 to August 6, 2005, using Agave 500-B5 and 500-B9 helicopters, C-130C, and C-765C.

Gamma-ray Spectrometric Data

The airborne gamma-ray measurements were made with an Epsilon-1000 gamma-ray spectrometer using 102 x 102 x 4.04 mm (4") crystals. The main detector array consisted of eight crystals (total volume 32.8 litres). One crystal (total volume 4.2 litres) shielded by the main array was used to detect variations in background radiation caused by atmospheric radon. The system constantly monitored the natural potassium peak for each crystal, and using a Gaussian least squares algorithm, adjusted the gain for each crystal.

Potassium is measured directly from the 1460 keV gamma-ray photons emitted by ⁴⁰K, whereas uranium and thorium are measured indirectly from gamma-ray photons emitted by daughter products (Pb-214 for uranium and Th-232 for thorium). Although these daughters are far from their respective decay chains, they are assumed to be in equilibrium with their parents. Thus gamma-ray spectrometric measurements of uranium and thorium are referred to as equivalent uranium and equivalent thorium, 1e and 4Th. The energy spectra used to measure potassium, uranium and thorium are:

Potassium (40K) 1460 - 1480 keV
Uranium (Th-232) 2600 - 2800 keV
Thorium (Th-232) 2410 - 2810 keV

Gamma-ray spectra were recorded at one-second intervals at a planned terrain clearance of 120m or 80m depending on the survey area and an air speed of 120km/h. The total potassium, uranium and thorium window counts were derived from the recorded 256 channel spectra. During processing, the spectra were energy calibrated, and counts were accumulated into the window described above. Counts from the main detector were recorded in a 1460 - 1480 keV window and radiation averages greater than 9000 cps were recorded in the cosmic window. The window counts were corrected for dead time and for background activity from cosmic radiation, the radioactivity of the aircraft and atmospheric radon decay products. The window data were then corrected for spectral peaking to the ground, air and detector. Corrections for elevation of altitude from the planned terrain clearance and for variation of temperature and pressure were made prior to conversion to gross concentrations of potassium, uranium and thorium, using factors determined from flights over a calibration range near Ottawa.

Potassium 0.2 x 10⁶ cps/km² (0.004 kg/m²)
Uranium 0.7 x 10⁶ cps/km² (0.004 kg/m²)
Thorium 0.8 x 10⁶ cps/km² (0.004 kg/m²)

Corrected data were filtered and interpolated to a 100m grid for the 1:50 000 scale maps and to a 50m grid for the 1:20 000 and 1:10 000 scale maps. The results of an airborne gamma-ray spectrometric survey represent the average surface concentrations that are influenced by varying amounts of outcrop, overburden, vegetation cover, and moisture and surface water. As a result, the measured concentrations are usually lower than the actual bedrock concentrations. The total air detector dose rate in readings per hour was produced from measured counts between 410 and 2810 keV.

Magnetic Data

The helicopter was equipped with a Scripps CS-2 cesium vapour magnetic sensor mounted in a 1041 high-resolution single sensor, single mounted system. The system recorded readings every 0.5 seconds with a noise level of less than 0.10 nT. Magnetic interference caused by aircraft movements were compensated using an EMI-1000 Magnetic compensator. Diurnal variations and GPS fluctuations were recorded using a Fugro GPS base station.

After editing the survey data, the intersections of traverse and control lines were determined and the differences in the magnetic values were corrected, analysed and manually verified to obtain the leveling network. The International Geomagnetic Reference Field was calculated and removed using a field date of October 15, 2004 and an altitude of the differentially corrected GPS height for each data point. The corrected magnetic data was interpolated to a 50m grid using a minimum curvature algorithm. The final vertical intensity grid was calculated from the corrected total magnetic intensity grid using a FFT based frequency domain filtering algorithm.

Positional Data

Line spacing and direction for survey and control lines were selected for each block to ensure the best interpretation of local geological features. Terrain clearance was monitored by scale elevation. Positional data were recorded using a dual frequency Novatel Millennium system. GPS synchronization data were combined with airborne GPS data to produce differentially corrected positional data with an accuracy of 2 to 5 m.

Data Presentation

Colour levels and contours were calculated for each grid and combined with map surround information to create postscript plot files, which were plotted using HP DesignJet colour plotters.
