FLOTATION OF COPPER FROM A TALCOSE ORE, HARVEY HILL DEPOSIT, LEEDS TOWNSHIP, MEGANTIC COUNTY, QUEBEC

Ъy

A. Stemerowicz* and R. W. Bruce**

_ - - -

SUMMARY OF RESULTS

The talcose ore investigated in the pilot-plant contained 1.44% copper in the form of chalcopyrite, bornite and chalcocite. Flotation at a grind of 51% minus 200 mesh gave a copper concentrate assaying 36.2% copper and 6.9% insolubles with a copper recovery of 96.6%. These results were achieved using Depramin 75 as talc depressant along with small amounts of amyl xanthate as collector and Dowfroth 250 as frother.

FLOTTATION D'UN MINERAI DE CUIVRE À HAUTE TENEUR EN TALC DU GISEMANT D' HARVEY HILL CANTON DE LEEDS, COMTE DE MÉGANTIC, QUÉBEC.

PAR

A. STEMEROWICZ* ET R. W. BRUCE**

RESUME

Les auteurs ont fait une étude en usine-pilote sur un minerai talceux contenant 1.44% de cuivre sous forme de chalcopyrite, de bornite et chalcosine. A la suite d'essais de flottation à un broyage de 51% moins 200 mailles, ils ont pu obtenir un concentré contenant 36.2% de cuivre et 6.9% de matière insoluble avec une récupération en cuivre de 96.6%. Ils ont obtenu de tels resultats en se servant du "Depramin 75" pour déprimer le talc, ainsi que de petites quantités d'amyl xanthate comme collecteur et de "Dowfroth 250" comme moussant.

* Chercheur scientifique et ** Chef de la section des mineraux non-ferreux, Division du traitement des minéraux, Direction des mines, Ministère de l'Energie, des Mines et des Ressources, Ottawa, Canada.

INTRODUCTION

Location of Property

The property which is known as the "Harvey Hill" deposit is located in Leeds Township, Megantic County Quebec, about five miles from Thetford Mines. <u>Shipment</u>

Three shipments of ore were received as follows:

Date	<u>Sample</u>	Weight	Remarks
September 21, 1972 October 2, 1972	No. 1 (high talc) No. 2 (low talc)	64 1b 60 1b	for bench-scale tests
October 12, 1972	Bulk	19.5 tons	for pilot-plant in- vestigations

Nature of Investigation Requested

In a letter of August 29, 1972 from Dr. R. A. Marleau, President, Marval Mines Inc. a pilot-plant investigation was requested on ore from the Harvey Hill deposit. Bench-scale work carried out by Mr. D. A. Livingstone in 1955-56 indicated that, at a coarse grind of 50% minus 200 mesh, the ore could be concentrated by flotation to give a copper concentrate grading 42% copper with a copper recovery of 95% on a 1.5% copper head. As Dr. Marleau planned to put the property into production, he wished to confirm Mr. Livingstone's work in order to establish mill equipment requirements.

Before proceeding with a pilot-plant investigation, it was desirable to carry out some bench-scale tests in order to become familiar with the flotation characteristics of the ore. Two samples were submitted for this purpose, a high-talc sample and a low-talc sample.

Sampling and Analysis

The two small samples were air dried, crushed in stages to minus 10 mesh and riffled into 16 portions. One of the portions was chosen at random as a head sample while the remaining portions made up the charges for batch tests. The large bulk sample was crushed in two stages to about minus $1\frac{1}{2}$ inches and stored in a pile on the receiving floor. During the course of crushing, the crushed ore stream was automatically sampled to give a head sample amounting to about 2% of the weight of the ore. This sample was set aside for possible future reference. The pile of minus $1\frac{1}{2}$ -inch ore was moved once with a front-end loader to ensure thorough mixing. Daily pilot plant requirements were taken from this pile and further crushed to minus 3/8 inch, a suitable size for feeding to the ball mill.

Head sample analyses are given in Table 1 followed by a semiquantitative spectrochemical analysis of Sample No. 2 in Table 2.

Mineralogical Examination

As previous work had indicated that the copper sulphides were

liberated at a coarse grind, mineralogical examination of the samples was not considered essential to the investigation. In a letter from Mr. Jean Boissonnault, geological consultant for Marval Mines, it was stated that the ore minerals were bornite, chalcocite and chalcopyrite while the gangue minerals consisted of quartz, feldspar, chlorite, sericite, some pyrite, talc and carbonates.

BENCH-SCALE INVESTIGATION

Outline of Investigation

In the initial tests on Sample No. 1 (high talc), it became apparent that satisfactory flotation of the copper sulphides could not be achieved without the use of an effective depressant. Two talc depressants were tried; Orzan A, which is the Crown Zellerbach Corp. trade name for ammonium lignin sulphonate, and Depramin, an anionic polymer sold by Hollimex Products Co. Ltd., # 509, 10201-104 Street, Edmonton 14, Alberta. Two grades of Depramin were tested, viz., Depramin 40 and Depramin 75. For maximum effectiveness it was necessary to feed this reagent in two stages; (1) to a conditioning step before the addition of collector and (2) after the rougher froth had been skimmed for two minutes.

The first test on Sample No. 2 (low-talc) gave satisfactory results without the aid of a talc depressant. Therefore, it only remained to carry out a parallel test employing the talc depressant, Depramin 75, to determine what effect, if any, this reagent had on this type of ore.

In all tests, potassium amyl xanthate was employed as the copper collector along with Dowfroth 250 as the frother. Early in the investigation, the practice was adopted of adding lime to the grind to ensure pyrite depression.

- 3 -

During the course of the investigation, the grind (as measured by the screen analysis of the rougher tailing) was varied from 56 to 79% minus 200 mesh.

The high talc content in the first sample greatly increased the viscosity of the ground pulp such that it was necessary to reduce the density in the lab rod mill from a standard 65% solids to 50% solids to ensure a fluid pulp.

Full details of all tests are given in Appendix A. Evaluation and Discussion of Results

Results achieved on the high-talc sample using Depramin 75 as the depressant for talc (Test 9) are given in Table 3 while the results obtained on the low-talc sample without the aid of a talc depressant (Test 10) are shown in Table 4.

TABLE 3

Feed (calcd)	100.00	2.08	19.20	100.0
Copper rougher conc.	5,58	36.62		98.2

Results Obtained on Low-Talc Sample without the Aid of a Talc Depressant (Test 10)

In both of the above tests, a coarse grind was employed; 56% and 59% minus 200 mesh in Tests 9 and 10 respectively. The copper lost in the tailing in Test 9 is higher than that obtained in other tests on the same sample and using similar procedure. For example, in Test 7, at the same grind, the copper content in the tailing was 0.08%. The only difference between the two tests was in the total amount of collector added; 0.0072 lb/ton in Test 9 as against 0.008 lb/ton in Test 7. It is possible that the difference was great enough to affect copper losses in the tailing.

Orzan A versus Depramin as Talc Depressant

Table 5 compares results obtained using Orzan A and Depramin as talc depressants on the high-talc sample.

TABLE 5

Orzan A versus Depramin as Talc Depressant

5	Depramin 40, 0.69	5.72	33.68	17.60	0.09	
8	Depramin 75, 0.69	6.40	34.45	22.68	0.12	

Comparison of Results Orzan A versus Depramin as Talc Depressant

* Products not analyzed.

From the above table it can be seen that Depramin is much superior to Orzan A as a talc depressant. In Test 1 the very high weight of copper rougher concentrate produced is a measure of the excessive amount of talc which floats when a talc depressant is not added.

Initially, Depramin 40 was used as the talc depressant. A switch was made to Depramin 75 afterit was learned that a large enough sample of this grade was on hand to satisfy pilot-plant requirements. Both grades appeared to be equally effective as talc depressants.

Although a talc depressant was not required on the low-talc sample, a relatively small but significant improvement in concentrate grade was obtained when one was employed. Referring to Tests 10 and 11, grade of copper concentrate was improved from 46.49% copper and 5.04% insolubles to 48.11% copper and 3.20% insolubles upon the addition of Depramin 75.

Effect of Fineness of Grind

No significant difference in results was noted as the fineness of grind was varied from 79% to 50% minus 200 mesh.

PILOT-PLANT INVESTIGATION

Outline of Investigation

After the initial test run on October 17, the purpose of which was to fill the grinding and flotation circuits and to observe the flotation behaviour of the sample, 9 test runs were carried out before the supply of ore was exhausted on November 1, 1972.

A feed rate of 500 lb/hr was employed in the first three test runs and this was increased to 600 lb/hr for the remaining test runs. Duration of the test runs ranged from $5\frac{1}{2}$ to $7\frac{1}{4}$ hours. Samples of various products were taken once every $\frac{1}{2}$ hour during the last $1\frac{1}{2}$ to 2 hours of the test run when it was assumed that conditions had stabilized. Sample preparation and analysis were done by Mines Branch personnel on an overtime basis following the completion of each test run.

All concentrates produced in the pilot plant were saved, filtered and stored in drums.

In the initial test run, it immediately became apparent that the bulk sample submitted was of the high-talc variety requiring the use of a talc depressant. Pilot-plant test procedure, therefore, was based on that employed in the batch tests on the high-talc sample but with two important differences:

(1) It was necessary to increase the initial addition of Depramin 75 by 50% (from 0.42 to 0.68 lb/ton) in order to completely depress the talc. (2) Rougher flotation had to be split into two stages with the froth from the second or scavenger stage recirculated to rougher feed whereas in lab batch tests, all of the rougher froth was combined and cleaned to give a finished grade of copper concentrate.

A further departure from batch test procedure was the addition of Depramin to the cleaners. This practice was adopted after cleaning tests on samples of pilot-plant rougher concentrate indicated that the use of Depramin resulted in an appreciable improvement in copper cleaner concentrate grade.

Test runs were conducted at grinds ranging from 49 to 76% minus 200 mesh. A 30-inch-diameter Sweco vibrating screen was used as the classifier. Because of the deceptive ease with which the ore was ground, many reductions in ball load were required in order to coarsen the grind to the desired 50% minus 200 mesh (ball load was reduced in 4 steps from an initial 1100 lb to 400 lb).

Detailed test procedure, metallurgical balances and pilot-plant flowsheets are given in Appendix B.

Evaluation and Discussion of Results

Best Results Using Coarse Grind

The best results obtained at a coarse grind of 51% minus 200 mesh are given below in Table 6.

- 8 -

TABLE 6

Product	Wt		alysis		Distn %	
	%	Cu	Insol	Ag	Cu	Ag

Feed (calc)	100.00	1.42		0,30	100.0	100.0
Copper rougher conc.		34.23	9.14			
lst stage Cu cleaner conc		35.49	6.70			

Best Results Obtained at a Coarse Grind (Test Run No.9)

* Additional analyses, Fe: 23.21%, S: 30.01%

As can be seen from the above table, excellent results can be obtained on this ore at a coarse grind and using Depramin 75 as talc depressant. In fact, selectivity between the sulphides and gangue minerals was so good in the roughers that the rougher concentrate (34.23% Cu, 9.14% Insol) could be taken as the final concentrate.

Note that the grade of copper concentrate is not as high as that obtained in batch tests although the insolubles content is in the same range. This would indicate that the proportion of bornite and chalcocite in the pilot-plant bulk sample is lower than in the smaller samples submitted for batch tests.

Initial Results Using Fine Grind

Excellent results were immediately obtained at a fine grind (71^{-to} 75% minus 200 mesh) in the early part of the investigation in Test Runs 2 and 3. Copper concentrates produced in these two test runs assayed 39.0% and 35.6% copper with copper recoveries of 98.1% and 96.7% respectively. Therefore, it appeared that it only remained to coarsen the grind to 50% minus 200 mesh, conduct a few test runs at this grind, and then the investigation could be brought to a successful conclusion. This, however, was not the case. Not only did it require many reductions in ball load to achieve the desired coarse grind but, starting with Test Run No. 4, copper concentrate grade began to deteriorate and it was not until the final test run (No. 9) that copper concentrate grade was on a par with that obtained in Test Runs 2 and 3.

Effect of Froth Characteristics on Concentrate Grade

The deterioration in concentrate grade was related to froth characteristics in the rougher cells. It was found that a "loose" freeflowing, voluminous froth resulted in a high content of insolubles in the copper rougher concentrate. This was because there was much more bubble surface area available than was required for sulphide attachment with the result that the extra space was taken up by talc particles and mica flakes. The "loose" froth condition was caused primarily by the addition to the first rougher of an insufficient amount of xanthate. By increasing the xanthate addition, the froth characteristics could be modified to give a "tight" well-mineralized froth. With this type of froth there was a considerable reduction in froth volume which resulted in all the available space on the bubble surfaces being occupied by copper sulphides which "crowded" out the less floatable gangue particles. If, however, a slight excess of xanthate was added the froth bed would be transformed into a thin layer of heavily-mineralized scum which could not be separated from the pulp.

It was possible by careful adjustment of xanthate feed rate to

- 10 -

obtain a well-mineralized but free-flowing froth in the roughers but this condition could not be maintained during the duration of the sampling period. Usually after about half an hour or so of steady operation, the froth would either become too loose or too scummy. In an attempt to overcome this problem an "on-off" method of controlling xanthate feed rate was adopted. This practice, which was successfully employed in Test Run No. 9, consisted of keeping a careful watch on froth conditions in the roughers. At the first sign that the froth was becoming scummy, the xanthate feeder was shut off for 1 or 2 minutes in order to "loosen" the froth. If, on the other hand, the froth showed signs of becoming too loose and free-flowing, an extra addition of xanthate (5 to 10 cc) was made manually in order to "tighten" the froth.

It is believed that the difficulty in maintaining the desired froth characteristics in the pilot plant was related to the scale of operation. For instance, the rate at which the rougher froth was being formed in the rougher cells was sufficient to give an intermittent froth overflow only (cells overflowing about half the time). Any disturbance, such as sampling of the recirculated scavenger concentrate, which involved cutting off all of the flow for one minute would be enough at times to "tighten" the froth, preventing overflow and resulting in a transformation to a "scummy" condition.

The fineness of the grind also had an effect on maintenance of the desired froth characteristics. When a fine grind was employed, the more finely-ground sulphides would have a greatly increased surface area requiring a much greater bubble area for attachment thus making the achievement of a well-mineralized froth a lot less difficult. This is, perhaps, one of the reasons the problem of froth characteristics did not manifest

- 11 -

itself in the early part of the investigation when a fine grind was being employed.

Generally, the character of the froth is an important factor in all types of sulphide flotation but is especially critical for this ore because of the ready floatability of talc and mica.

Effect of Fineness of Grind

Loss of copper in the tailing was constant at 0.05% to 0.06% throughout the investigation indicating that the coarsest grind employed (49% minus 200 mesh) was adequate for essentially complete liberation of the sulphides from the gangue. Other than its effect on froth characteristics noted above, the fineness of grind in the range employed did not have any significant effect on concentrate grade.

As a screen was used for classification the sulphides in the ground ore were coarser than would be the case for classification with a mechanical classifier or cyclone. This is because the latter two devices classify by gravity and not by particle size as does the screen. Gravity classification results in the concentration of the larger sulphide particles in the underflow fraction and subsequent overgrinding.

Effect of Depramin in Cleaning

Table 7 compares results of batch cleaning tests, with and without the addition of Depramin 75, on pilot-plant rougher concentrates produced in Test Run No. 1. Included in the comparison are the cleaning circuit results for Test Run No. 1

- 12 -

Comparison of Results for Batch Cleaning Tests on Pilot-Plant Copper Rougher Concentrate

* Per ton of cleaner feed

** Separation efficiency, % copper recovered minus % insolubles recovered in cleaner concentrate.

As can be seen from the above comparison the addition of Depramin 75 to the copper cleaner in Batch Test P-2 resulted in a substantial increase in concentrate grade. For this reason, the practice was adopted of feeding Depramin to the copper cleaner starting with Test Run No. 3, but at only about half the feed rate (0.40 to 0.55 lb per ton of cleaner feed). Whether or not Depramin was beneficial in the pilot plant at this level is open to question but, judging from the difficulty experienced in upgrading the rougher concentrate, it would appear that this

Lime as Pyrite Depressant

It was not possible by iron analysis to determine the effectiveness of lime as a pyrite depressant but when the final tailing was run over a Wilfley table a pyrite streak was visible indicating that it was being depressed. Whether or not it was possible to obtain satisfactory results without the addition of lime was not determined.

Distribution of Insolubles in Various Size Fractions of Copper Concentrate

Tables 8 and 9 give the distribution of copper and insolubles in various size fractions of low-grade copper concentrate from Test Run No. 7 and high-grade copper concentrate from Test Run No. 9 respectively.

TABLE 8

Total	100.0	36.22	7.53	100.0	100.0

Distribution of Insolubles in Various Size Fractions of High-Grade Copper Concentrate from Test Run No. 9

From the above tables, it can be seen that the intermediate size fractions have the lowest insolubles content, whereas the coarsest fractions and the minus 325 mesh fraction contain the highest amount of insolubles. The size fractions were not submitted for mineralogical examination but, by visual examination, it can be seen that the coarse fractions are contaminated by mica flakes. Presumably, the insoluble content in the minus 325-mesh fraction is due to talc.

The grinding characteristics of this high-talc ore are unusual in that the gangue minerals are preferentially ground finer than the sulphides. Generally, for other types of sulphide ores the opposite is true. Table 10 gives a comparison of screen analyses of the ground ore (screen undersize) and copper concentrate for Test Runs 7 and 9.

Comparison of Screen Analyses of Screen Undersize and Concentrate

Flotation Capacity

The flotation capacity employed in Test Run No. 9 (Flowsheet No. 4) is given in Table 11.

TABLE 11

Flotation Capacity Employed in Test Run No. 9 (Flowsheet No. 4)

Operation	Units		Contact time	Density % Sol
		per ton	min*	% 301 :
Conditioning	1- No. 7 Denver cells @ 0.87 cu ft	0.12	21/2	35
Rougher Flotation	2- " " " " " " "	0.24	5	35
Scavenger Flotation	5- " " " " " " " "	0.60	12	35
lst Stage Cleaner	4-No. 5 Denver cells @ 0.23 cu ft	0.13	19	12
2nd Stage Cleaner	3 " " " " " " " "	0.10	12	10

*Calculations based on assumed S.G. of 2.8 for feed to rougher and scavenger flotation and S.G. of 4.0 for cleaner feed.

The pulp contact time of 17 minutes in the rougher and scavengers corresponds to a skimming time of 5 minutes in lab batch tests and appears to be a reasonable figure for a full-scale plant. An increase of about 25% in flotation capacity to about 1 cu ft/ton treated might be warranted to take care of a higher copper head.

Note that in Test Run No. 9 the third scavenger cell tailing assayed 0.08%. It thus required 2 additional cells or a 40% increase in flotation capacity to reduce the tailing to its final value of 0.05% copper. This is equivalent to the recovery of an additional 0.6 lb of copper per ton treated and on this basis it would appear that the additional flotation capacity required to achieve the lower tailing is economically justified.

The first-stage cleaner cell capacity employed in the pilot plant, viz., 0.13 cu ft/ton treated, is in the range used in full-scale flotation plants. As is evident from the results obtained in Test Run No. 9, a second stage of cleaning is not required.

CONCLUSIONS

Despite the high talc content, a high-grade copper concentrate with excellent recovery can be produced from this ore at a coarse grind of 50% minus 200 mesh. This confirms the results obtained by Mr. Livingstone in work carried out in 1955-56.

The key to success in treating the high-talc ore was the effectiveness of Depramin 75 as a talc depressant along with the maintenance of a heavily mineralized but free-flowing rougher froth. Because froth characteristics are so important it is recommended that an air-injected type of flotation cell be employed in the full-scale plant. This will allow for much closer control over froth characteristics.

As was mentioned previously, the high-talc ore was found extremely easy to grind and therefore grinding costs should be very low.

- 17 -

No attempt was made to measure power consumption for grinding because, from previous experience, it had been found that there was no significant difference between the power consumed by the pilot-plant ball mill when it was running empty and with the feed on. The talc in the ore affects the viscosity of the pulp such that, for pulp densities beyond about 60% solids, the pulp ceases to become fluid. Because of this limitation, ball mill capacity would be reduced, but this should be more than offset by the ease with which the ore can be ground.

The grade of the copper concentrate that can be produced from this ore will vary, depending on the chalcocite-bornite to chalcopyrite ratio in the mill feed. As this ratio increases so will the grade of the final copper concentrate.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the assistance of members of the staff of the Metallic Minerals Mill, Mineral Processing Division, who, under the direction of Mr. A. J. Boisonnault, set up the pilot-plant equipment and assisted in its operation.

They also wish to thank the following members of the Analytical Chemistry Subdivision of the Mineral Sciences Division: Messrs J. Cloutier, D. Cumming, B. Kobus, P. Lanthier and A. Letendre who, under the direction of Mr. J. C. Hole, carried out the chemical analyses; Mr. J. Graham who did the fire assaying for gold and silver; and Mr. D. P. Polombo who did the semi-quantitative spectrochemical analysis.
